percent) and in prison populations, where the prevalence may be as high as 75 percent. It is much more common in males than in females. Boys with the disorder come from larger families than girls with the disorder. The onset of the disorder is before the age of 15 years. Girls usually have symptoms before puberty and boys even earlier. A familial pattern is present; the disorder is five times more common among first-degree relatives of men with the disorder than among control participants.

**Diagnosis**

Patients with antisocial personality disorder can fool even the most experienced clinicians. In an interview, patients can appear composed and credible, but beneath the veneer (or, to use Hervey Cleckley’s term, *the mask of sanity*) lurks tension, hostility, irritability, and rage. A stress interview, in which patients are vigorously confronted with inconsistencies in their histories, may be necessary to reveal the pathology.

A diagnostic workup should include a thorough neurological examination. Because patients often show abnormal EEG results and soft neurological signs suggesting minimal brain damage in childhood, these findings can be used to confirm the clinical impression. The DSM-5 diagnostic criteria are listed in Table 22-4.

**Clinical Features**

Patients with antisocial personality disorder can often seem to be normal and even charming and ingratiating. Their histories, however, reveal many areas of disordered life functioning. Lying, truancy, running away from home, thefts, fights, substance
abuse, and illegal activities are typical experiences that patients report as beginning in childhood. These patients often impress opposite-sex clinicians with the colorful, seductive aspects of their personalities, but same-sex clinicians may regard them as manipulative and demanding. Patients with antisocial personality disorder exhibit no anxiety or depression, a lack that may seem grossly incongruous with their situations, although suicide threats and somatic preoccupations may be common. Their own explanations of their antisocial behavior make it seem mindless, but their mental content reveals the complete absence of delusions and other signs of irrational thinking. In fact, they frequently have a heightened sense of reality testing and often impress observers as having good verbal intelligence.

Persons with antisocial personality disorder are highly representative of so-called con men. They are extremely manipulative and can frequently talk others into participating in schemes for easy ways to make money or to achieve fame or notoriety. These schemes may eventually lead the unwary to financial ruin or social embarrassment or both. Those with this disorder do not tell the truth and cannot be trusted to carry out any task or adhere to any conventional standard of morality. Promiscuity, spousal abuse, child abuse, and drunk driving are common events in their lives. A notable finding is a lack of remorse for these actions; that is, they appear to lack a conscience.

Differential Diagnosis

Antisocial personality disorder can be distinguished from illegal behavior in that antisocial personality disorder involves many areas of a person’s life. When illegal behavior is only for gain and is not accompanied by the rigid, maladaptive, and persistent personality traits characteristic of a personality disorder, it is classified as criminal behavior not associated with a personality disorder according to DSM-5.

Dorothy Lewis found that many of these persons have a neurological or mental disorder that has been either overlooked or undiagnosed. More difficult is the differentiation of antisocial personality disorder from substance abuse. When both substance abuse and antisocial behavior begin in childhood and continue into adult life, both disorders should be diagnosed. When, however, the antisocial behavior is clearly secondary to premorbid alcohol abuse or other substance abuse, the diagnosis of antisocial personality disorder is not warranted.

In diagnosing antisocial personality disorder, clinicians must adjust for the distorting effects of socioeconomic status, cultural background, and sex. Furthermore, the diagnosis of antisocial personality disorder is not warranted when intellectual disability, schizophrenia, or mania can explain the symptoms.

Course and Prognosis

When an antisocial personality disorder develops, it runs an unremitting course, with the height of antisocial behavior usually occurring in late adolescence. The prognosis varies. Some reports indicate that symptoms decrease as persons grow older. Many patients have somatization disorder and multiple physical complaints. Depressive
disorders, alcohol use disorders, and other substance abuse are common.

**Treatment**

**Psychotherapy.** If patients with antisocial personality disorder are immobilized (e.g., placed in hospitals), they often become amenable to psychotherapy. When patients feel that they are among peers, their lack of motivation for change disappears. Perhaps for this reason, self-help groups have been more useful than jails in alleviating the disorder.

Before treatment can begin, firm limits are essential. Therapists must find ways of dealing with patients’ self-destructive behavior. And to overcome patients’ fear of intimacy, therapists must frustrate patients’ desire to run from honest human encounters. In doing so, therapists face the challenge of separating control from punishment and of separating help and confrontation from social isolation and retribution.

**Pharmacotherapy.** Pharmacotherapy is used to deal with incapacitating symptoms such as anxiety, rage, and depression, but because patients are often substance abusers, drugs must be used judiciously. If a patient shows evidence of attention-deficit/hyperactivity disorder, psychostimulants such as methylphenidate (Ritalin) may be useful. Attempts have been made to alter catecholamine metabolism with drugs and to control impulsive behavior with antiepileptic drugs, for example, carbamazepine (Tegretol) or valproate (Depakote), especially if abnormal waveforms are noted on an EEG. β-Adrenergic receptor antagonists have been used to reduce aggression.

**BORDERLINE PERSONALITY DISORDER**

Patients with borderline personality disorder stand on the border between neurosis and psychosis, and they are characterized by extraordinarily unstable affect, mood, behavior, object relations, and self-image. The disorder has also been called *ambulatory schizophrenia, as-if personality* (a term coined by Helene Deutsch), *pseudoneurotic schizophrenia* (described by Paul Hoch and Phillip Politan), and *psychotic character disorder* (described by John Frosch). The 10th revision of the *International Classification of Diseases* 10 (ICD-10) uses the term *emotionally unstable personality disorder*.

**Epidemiology**

No definitive prevalence studies are available, but borderline personality disorder is thought to be present in about 1 to 2 percent of the population and is twice as common in women as in men. An increased prevalence of major depressive disorder, alcohol use disorders, and substance abuse is found in first-degree relatives of persons with borderline personality disorder.
Diagnosis

According to DSM-5, the diagnosis of borderline personality disorder can be made by early adulthood when patients show at least five of the criteria listed in Table 22-5. Biological studies may aid in the diagnosis; some patients with borderline personality disorder show shortened REM latency and sleep continuity disturbances, abnormal DST results, and abnormal thyrotropin-releasing hormone test results. Those changes, however, are also seen in some patients with depressive disorders.

Clinical Features

Persons with borderline personality disorder almost always appear to be in a state of crisis. Mood swings are common. Patients can be argumentative at one moment, depressed the next, and later complain of having no feelings. Patients can have short-lived psychotic episodes (so-called micropsychotic episodes) rather than full-blown psychotic breaks, and the psychotic symptoms of these patients are almost always circumscribed, fleeting, or doubtful. The behavior of patients with borderline personality disorder is highly unpredictable, and their achievements are rarely at the level of their abilities. The painful nature of their lives is reflected in repetitive self-destructive acts. Such patients may slash their wrists and perform other self-mutilations to elicit help from others, to express anger, or to numb themselves to overwhelming affect.
Because they feel both dependent and hostile, persons with this disorder have tumultuous interpersonal relationships. They can be dependent on those with whom they are close and, when frustrated, can express enormous anger toward their intimate friends. Patients with borderline personality disorder cannot tolerate being alone, and they prefer a frantic search for companionship, no matter how unsatisfactory, to their own company. To assuage loneliness, if only for brief periods, they accept a stranger as a friend or behave promiscuously. They often complain about chronic feelings of emptiness and boredom and the lack of a consistent sense of identity (identity diffusion); when pressed, they often complain about how depressed they usually feel, despite the flurry of other affects.

Otto Kernberg described the defense mechanism of projective identification that occurs in patients with borderline personality disorder. In this primitive defense mechanism, intolerable aspects of the self are projected onto another; the other person is induced to play the projected role, and the two persons act in unison. Therapists must be aware of this process so they can act neutrally toward such patients.

Most therapists agree that these patients show ordinary reasoning abilities on structured tests, such as the Wechsler Adult Intelligence Scale, and show deviant processes only on unstructured projective tests, such as the Rorschach test.

Functionally, patients with borderline personality disorder distort their relationships by considering each person to be either all good or all bad. They see persons as either nurturing attachment figures or as hateful, sadistic figures who deprive them of security needs and threaten them with abandonment whenever they feel dependent. As a result of this splitting, the good person is idealized and the bad person devalued. Shifts of allegiance from one person or group to another are frequent. Some clinicians use the concepts of panphobia, pananxiety, panambivalence, and chaotic sexuality to delineate these patients’ characteristics.

**Differential Diagnosis**

The disorder is differentiated from schizophrenia on the basis that the patient with borderline personality lacks prolonged psychotic episodes, thought disorder, and other classic schizophrenic signs. Patients with schizotypal personality disorder show marked peculiarities of thinking, strange ideation, and recurrent ideas of reference. Those with paranoid personality disorder are marked by extreme suspiciousness. Patients with borderline personality disorder generally have chronic feelings of emptiness and short-lived psychotic episodes; they act impulsively and demand extraordinary relationships; they may mutilate themselves and make manipulative suicide attempts.

**Course and Prognosis**

Borderline personality disorder is fairly stable; patients change little over time. Longitudinal studies show no progression toward schizophrenia, but patients have a high incidence of major depressive disorder episodes. The diagnosis is usually made before the age of 40 years, when patients are attempting to make occupational, marital,
and other choices and are unable to deal with the normal stages of the life cycle.

**Treatment**

**Psychotherapy.** Psychotherapy for patients with borderline personality disorder is an area of intensive investigation and has been the treatment of choice. For best results, pharmacotherapy has been added to the treatment regimen.

Psychotherapy is difficult for the patient and therapist alike. Patients regress easily, act out their impulses, and show labile or fixed negative or positive transferences, which are difficult to analyze. Projective identification may also cause countertransference problems when therapists are unaware that patients are unconsciously trying to coerce them to act out a particular behavior. The splitting defense mechanism causes patients to alternately love and hate therapists and others in the environment. A reality-oriented approach is more effective than in-depth interpretations of the unconscious.

Therapists have used behavior therapy to control patients’ impulses and angry outbursts and to reduce their sensitivity to criticism and rejection. Social skills training, especially with videotape playback, helps enable patients to see how their actions affect others and thereby improve their interpersonal behavior.

Patients with borderline personality disorder often do well in a hospital setting in which they receive intensive psychotherapy on both an individual and a group basis. In a hospital, they can also interact with trained staff members from a variety of disciplines and can be provided with occupational, recreational, and vocational therapy. Such programs are especially helpful when the home environment is detrimental to a patient’s rehabilitation because of intrafamilial conflicts or other stresses, such as parental abuse. Within the protected environment of the hospital, patients who are excessively impulsive, self-destructive, or self-mutilating can be given limits, and their actions can be observed. Under ideal circumstances, patients remain in the hospital until they show marked improvement, up to 1 year in some cases. Patients can then be discharged to special support systems, such as day hospitals, night hospitals, and halfway houses.

**DIALECTICAL BEHAVIOR THERAPY.** A particular form of psychotherapy called dialectical behavior therapy (DBT) has been used for patients with borderline personality disorder, especially those with parasuicidal behavior, such as frequent cutting. For further discussion of DBT, see Section 29.5 in Chapter 29.

**MENTALIZATION-BASED TREATMENT.** Another type of psychotherapy for borderline personality disorder is called mentalization-based therapy (MBT). Mentalization is a social construct that allows a person to be attentive to the mental states of oneself and of others; it comes from a person’s awareness of mental processes and subjective states that arise in interpersonal interactions. MBT is based on a theory that borderline personality symptoms, such as difficulty regulating emotions and managing impulsivity, are a result of patients’ reduced capacities to mentalize. Thus, it is believed that recovery of mentalization helps patients build relationship skills as they learn to better
regulate their thoughts and feelings. MBT was found to be effective for borderline personality disorder in several randomized, controlled research trials.

TRANSCIENCE-FOCUSED PSYCHOTHERAPY. Transference-focused psychotherapy (TFP) is a modified form of psychodynamic psychotherapy used for the treatment of borderline personality disorder that is based on Otto Kernberg’s object relations theory. The therapist relies on two major processes in working with the patient: The first is clarification, in which the transference is analyzed more directly than in traditional psychotherapy so that the patient becomes quickly aware his or her distortions about the therapist. The second is confrontation, whereby the therapist points out how these transference distortions interfere with interpersonal relations toward others (objects). The mechanism of splitting used by borderline patients is characterized by their having a good object and a bad object and is used as a defense against anxiety. If therapy is successful, then the need for splitting diminishes, object relations are improved, and a more normal level of functioning is achieved. Studies comparing TFP, DBT, psychodynamic psychotherapy, and supportive psychotherapy show that all are useful and all show varying degrees of success. As yet, no consensus has been reached as to which, if any, of these is superior to the others.

Pharmacotherapy. Pharmacotherapy is useful to deal with specific personality features that interfere with patients’ overall functioning. Antipsychotics have been used to control anger, hostility, and brief psychotic episodes. Antidepressants improve the depressed mood common in patients with borderline personality disorder. The MAO inhibitors (MAOIs) have successfully modulated impulsive behavior in some patients. Benzodiazepines, particularly alprazolam (Xanax), help anxiety and depression, but some patients show a disinhibition with this class of drugs. Anticonvulsants, such as carbamazepine, may improve global functioning for some patients. Serotonergic agents such as selective serotonin reuptake inhibitors (SSRIs) have been helpful in some cases.

HISTRIONIC PERSONALITY DISORDER

Persons with histrionic personality disorder are excitable and emotional and behave in a colorful, dramatic, extroverted fashion. Accompanying their flamboyant aspects, however, is often an inability to maintain deep, long-lasting attachments.

Epidemiology

Limited data from general population studies suggest a prevalence of histrionic personality disorder of about 1 to 3 percent. Rates of about 10 to 15 percent have been reported in inpatient and outpatient mental health settings when structured assessment is used. The disorder is diagnosed more frequently in women than in men. Some studies have found an association with somatization disorder and alcohol use disorders.

Diagnosis
In interviews, patients with histrionic personality disorder are generally cooperative and eager to give a detailed history. Gestures and dramatic punctuation in their conversations are common; they may make frequent slips of the tongue, and their language is colorful. Affective display is common, but when pressed to acknowledge certain feelings (e.g., anger, sadness, and sexual wishes), they may respond with surprise, indignation, or denial. The results of the cognitive examination are usually normal, although a lack of perseverance may be shown on arithmetic or concentration tasks, and the patients’ forgetfulness of affect-laden material may be astonishing. DSM-5 diagnostic criteria are listed in Table 22-6.

Table 22.6  
DSM-5 Diagnostic Criteria for Histrionic Personality Disorder

A pervasive pattern of excessive emotionality and attention seeking, beginning in early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
1. Is uncomfortable in situations in which he or she is not the center of attention.
2. Interaction with others is often characterized by inappropriate sexually seductive or provocative behavior.
3. Displays rapidly shifting and shallow expression of emotions.
4. Consistently uses physical appearance to draw attention to self.
5. Has a style of speech that is excessively impressionistic and lacking in detail.
7. Is suggestible (i.e., easily influenced by others or circumstances).
8. Considers relationships to be more intimate than they actually are.

(Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Clinical Features

Persons with histrionic personality disorder show a high degree of attention-seeking behavior. They tend to exaggerate their thoughts and feelings and make everything sound more important than it really is. They display temper tantrums, tears, and accusations when they are not the center of attention or are not receiving praise or approval.

Seductive behavior is common in both sexes. Sexual fantasies about persons with whom patients are involved are common, but patients are inconsistent about verbalizing these fantasies and may be coy or flirtatious rather than sexually aggressive. In fact, histrionic patients may have a psychosexual dysfunction; women may be anorgasmic, and men may be impotent. Their need for reassurance is endless. They may act on their sexual impulses to reassure themselves that they are attractive to the other sex. Their relationships tend to be superficial, however, and they can be vain, self-absorbed, and fickle. Their strong dependence needs make them overly trusting and
The major defenses of patients with histrionic personality disorder are repression and dissociation. Accordingly, such patients are unaware of their true feelings and cannot explain their motivations. Under stress, reality testing easily becomes impaired.

**Differential Diagnosis**

Distinguishing between histrionic personality disorder and borderline personality disorder is difficult, but in borderline personality disorder, suicide attempts, identity diffusion, and brief psychotic episodes are more likely. Although both conditions may be diagnosed in the same patient, clinicians should separate the two. Somatization disorder (Briquet’s syndrome) may occur in conjunction with histrionic personality disorder. Patients with brief psychotic disorder and dissociative disorders may warrant a coexisting diagnosis of histrionic personality disorder.

**Course and Prognosis**

With age, persons with histrionic personality disorder show fewer symptoms, but because they lack the energy of earlier years, the difference in number of symptoms may be more apparent than real. Persons with this disorder are sensation seekers, and they may get into trouble with the law, abuse substances, and act promiscuously.

**Treatment**

**Psychotherapy.** Patients with histrionic personality disorder are often unaware of their own real feelings; clarification of their inner feelings is an important therapeutic process. Psychoanalytically oriented psychotherapy, whether group or individual, is probably the treatment of choice for histrionic personality disorder.

**Pharmacotherapy.** Pharmacotherapy can be adjunctive when symptoms are targeted (e.g., the use of antidepressants for depression and somatic complaints, antianxiety agents for anxiety, and antipsychotics for derealization and illusions).

**NARCISSISTIC PERSONALITY DISORDER**

Persons with narcissistic personality disorder are characterized by a heightened sense of self-importance, lack of empathy, and grandiose feelings of uniqueness. Underneath, however, their self-esteem is fragile and vulnerable to even minor criticism.

**Epidemiology**

According to DSM-5, estimates of the prevalence of narcissistic personality disorder range from less than 1 to 6 percent in community samples. Persons with the disorder may impart an unrealistic sense of omnipotence, grandiosity, beauty, and talent to their children; thus, offspring of such parents may have a higher than usual risk for
developing the disorder themselves.

**Diagnosis**

Table 22-7 gives the DSM-5 diagnostic criteria for narcissistic personality disorder.

### Table 22-7

DSM-5 Diagnostic Criteria for Narcissistic Personality Disorder

</tr>
<tr>
<td>9. Shows arrogant, haughty behaviors or attitudes.</td>
</tr>
</tbody>
</table>

(Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

**Clinical Features**

Persons with narcissistic personality disorder have a grandiose sense of self-importance; they consider themselves special and expect special treatment. Their sense of entitlement is striking. They handle criticism poorly and may become enraged when someone dares to criticize them, or they may appear completely indifferent to criticism. Persons with this disorder want their own way and are frequently ambitious to achieve fame and fortune. Their relationships are tenuous, and they can make others furious by their refusal to obey conventional rules of behavior. Interpersonal exploitativeness is commonplace. They cannot show empathy, and they feign sympathy only to achieve their own selfish ends. Because of their fragile self-esteem, they are susceptible to depression. Interpersonal difficulties, occupational problems, rejection, and loss are among the stresses that narcissists commonly produce by their behavior—stresses they are least able to handle.

**Differential Diagnosis**

Borderline, histrionic, and antisocial personality disorders often accompany narcissistic
personality disorder, so a differential diagnosis is difficult. Patients with narcissistic personality disorder have less anxiety than those with borderline personality disorder; their lives tend to be less chaotic, and they are less likely to attempt suicide. Patients with antisocial personality disorder have a history of impulsive behavior, often associated with alcohol or other substance abuse, which frequently gets them into trouble with the law. Patients with histrionic personality disorder show features of exhibitionism and interpersonal manipulativeness that resemble those of patients with narcissistic personality disorder.

Course and Prognosis
Narcissistic personality disorder is chronic and difficult to treat. Patients with the disorder must constantly deal with blows to their narcissism resulting from their own behavior or from life experience. Aging is handled poorly; patients value beauty, strength, and youthful attributes, to which they cling inappropriately. They may be more vulnerable, therefore, to midlife crises than are other groups.

Treatment
Psychotherapy. Because patients must renounce their narcissism to make progress, the treatment of narcissistic personality disorder is difficult. Psychiatrists such as Kernberg and Heinz Kohut have advocated using psychoanalytic approaches to effect change, but much research is required to validate the diagnosis and to determine the best treatment. Some clinicians advocate group therapy for their patients so they can learn how to share with others and, under ideal circumstances, can develop an empathic response to others.

Pharmacotherapy. Lithium (Eskalith) has been used with patients whose clinical picture includes mood swings. Because patients with narcissistic personality disorder tolerate rejection poorly and are susceptible to depression, antidepressants, especially serotonergic drugs, may also be of use.

AVOIDANT PERSONALITY DISORDER
Persons with avoidant personality disorder show extreme sensitivity to rejection and may lead socially withdrawn lives. Although shy, they are not asocial and show a great desire for companionship, but they need unusually strong guarantees of uncritical acceptance. Such persons are commonly described as having an inferiority complex.

Epidemiology
The prevalence of the disorder is suggested to be about 2 to 3 percent of the general population according to DSM-5. No information is available on sex ratio or familial pattern. Infants classified as having a timid temperament may be more susceptible to
the disorder than those who score high on activity-approach scales.

**Diagnosis**

In clinical interviews, patients’ most striking aspect is anxiety about talking with an interviewer. Their nervous and tense manner appears to wax and wane with their perception of whether an interviewer likes them. They seem vulnerable to the interviewer’s comments and suggestions and may regard a clarification or interpretation as criticism. The DSM-5 diagnostic criteria for avoidant personality disorder are listed in Table 22-8.

<table>
<thead>
<tr>
<th>Table 22-8</th>
<th>DSM-5 Diagnostic Criteria for Avoidant Personality Disorder</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Clinical Features</strong></td>
<td>Hypersensitivity to rejection by others is the central clinical feature of avoidant personality disorder, and patients’ main personality trait is timidity. These persons desire the warmth and security of human companionship but justify their avoidance of relationships by their alleged fear of rejection. When talking with someone, they express uncertainty, show a lack of self-confidence, and may speak in a self-effacing manner. Because they are hypervigilant about rejection, they are afraid to speak up in public or to make requests of others. They are apt to misinterpret other persons’ comments as derogatory or ridiculing. The refusal of any request leads them to withdraw from others and to feel hurt.</td>
</tr>
<tr>
<td></td>
<td>In the vocational sphere, patients with avoidant personality disorder often take jobs on the sidelines. They rarely attain much personal advancement or exercise much authority but seem shy and eager to please. These persons are generally unwilling to enter relationships unless they are given an unusually strong guarantee of uncritical</td>
</tr>
</tbody>
</table>
acceptance. Consequently, they often have no close friends or confidants.

**Differential Diagnosis**

Patients with avoidant personality disorder desire social interaction, unlike patients with schizoid personality disorder, who want to be alone. Patients with avoidant personality disorder are not as demanding, irritable, or unpredictable as those with borderline and histrionic personality disorders. Avoidant personality disorder and dependent personality disorder are similar. Patients with dependent personality disorder are presumed to have a greater fear of being abandoned or unloved than those with avoidant personality disorder, but the clinical picture may be indistinguishable.

**Course and Prognosis**

Many persons with avoidant personality disorder are able to function in a protected environment. Some marry, have children, and live their lives surrounded only by family members. If their support system fails, however, they are subject to depression, anxiety, and anger. Phobic avoidance is common, and patients with the disorder may give histories of social phobia or incur social phobia in the course of their illness.

**Treatment**

**Psychotherapy.** Psychotherapeutic treatment depends on solidifying an alliance with patients. As trust develops, a therapist must convey an accepting attitude toward the patient’s fears, especially the fear of rejection. The therapist eventually encourages a patient to move out into the world to take what are perceived as great risks of humiliation, rejection, and failure. But therapists should be cautious when giving assignments to exercise new social skills outside therapy; failure can reinforce a patient’s already poor self-esteem. Group therapy may help patients understand how their sensitivity to rejection affects them and others. Assertiveness training is a form of behavior therapy that may teach patients to express their needs openly and to enlarge their self-esteem.

**Pharmacotherapy.** Pharmacotherapy has been used to manage anxiety and depression when they are associated with the disorder. Some patients are helped by β-adrenergic receptor antagonists, such as atenolol (Tenormin), to manage autonomic nervous system hyperactivity, which tends to be high in patients with avoidant personality disorder, especially when they approach feared situations. Serotonergic agents may help rejection sensitivity. Theoretically, dopaminergic drugs might engender novelty-seeking behavior in these patients; however, the patient must be psychologically prepared for any new experience that might result.

**DEPENDENT PERSONALITY DISORDER**
Persons with dependent personality disorder subordinate their own needs to those of others, get others to assume responsibility for major areas of their lives, lack self-confidence, and may experience intense discomfort when alone for more than a brief period. The disorder has been called passive-dependent personality. Freud described an oral-dependent personality dimension characterized by dependence, pessimism, fear of sexuality, self-doubt, passivity, suggestibility, and lack of perseverance; his description is similar to the DSM-5 categorization of dependent personality disorder.

Epidemiology
Dependent personality disorder is more common in women than in men. DSM-5 reports an estimated prevalence of 0.6 percent. One study diagnosed 2.5 percent of all personality disorders as falling into this category. It is more common in young children than in older ones. Persons with chronic physical illness in childhood may be most susceptible to the disorder.

Diagnosis
In interviews, patients appear compliant. They try to cooperate, welcome specific questions, and look for guidance. The DSM-5 diagnostic criteria for dependent personality disorder are listed in Table 22-9.

Clinical Features
Dependent personality disorder is characterized by a pervasive pattern of dependent and submissive behavior. Persons with the disorder cannot make decisions without an excessive amount of advice and reassurance from others. They avoid positions of responsibility and become anxious if asked to assume a leadership role. They prefer to be submissive. When on their own, they find it difficult to persevere at tasks but may find it easy to perform these tasks for someone else.

Because persons with the disorder do not like to be alone, they seek out others on whom they can depend; their relationships, thus, are distorted by their need to be attached to another person. In folie à deux (shared psychotic disorder), one member of the pair usually has dependent personality disorder; the submissive partner takes on the delusional system of the more aggressive, assertive partner on whom he or she depends.

Pessimism, self-doubt, passivity, and fears of expressing sexual and aggressive feelings all typify the behavior of persons with dependent personality disorder. An abusive, unfaithful, or alcoholic spouse may be tolerated for long periods to avoid disturbing the sense of attachment.

Differential Diagnosis
The traits of dependence are found in many psychiatric disorders, so the differential diagnosis is difficult. Dependence is a prominent factor in patients with histrionic and borderline personality disorders, but those with dependent personality disorder usually have a long-term relationship with one person rather than a series of persons on whom they are dependent, and they do not tend to be overtly manipulative. Patients with schizoid and schizotypal personality disorders may be indistinguishable from those with avoidant personality disorder. Dependent behavior can also occur in patients with agoraphobia, but these patients tend to have a high level of overt anxiety or even panic.

Course and Prognosis
Little is known about the course of dependent personality disorder. Occupational functioning tends to be impaired because persons with the disorder cannot act independently and without close supervision. Social relationships are limited to those on whom they can depend, and many suffer physical or mental abuse because they cannot assert themselves. They risk major depressive disorder if they lose the person on whom they depend, but with treatment, the prognosis is favorable.

Treatment

Psychotherapy. The treatment of dependent personality disorder is often successful. Insight-oriented therapies enable patients to understand the antecedents of their behavior, and with the support of a therapist, patients can become more independent, assertive, and self-reliant. Behavioral therapy, assertiveness training, family therapy, and group therapy have all been used, with successful outcomes in many cases.
A pitfall may arise in treatment when a therapist encourages a patient to change the dynamics of a pathological relationship (e.g., supports a physically abused wife in seeking help from the police). At this point, patients may become anxious and unable to cooperate in therapy; they may feel torn between complying with the therapist and losing a pathological external relationship. Therapists must show great respect for these patients’ feelings of attachment, no matter how pathological these feelings may seem.

**Pharmacotherapy.** Pharmacotherapy has been used to deal with specific symptoms, such as anxiety and depression, which are common associated features of dependent personality disorder. Patients who experience panic attacks or who have high levels of separation anxiety may be helped by imipramine (Tofranil). Benzodiazepines and serotonergic agents have also been useful. If a patient’s depression or withdrawal symptoms respond to psychostimulants, they may be used.

**OBSESSIVE-COMPELLSIVE PERSONALITY DISORDER**

Obsessive-compulsive personality disorder is characterized by emotional constriction, orderliness, perseverance, stubbornness, and indecisiveness. The essential feature of the disorder is a pervasive pattern of perfectionism and inflexibility.

**Epidemiology**

DSM-5 reports an estimated prevalence ranging from 2 to 8 percent. It is more common in men than in women and is diagnosed most often in oldest siblings. The disorder also occurs more frequently in first-degree biological relatives of persons with the disorder than in the general population. Patients often have backgrounds characterized by harsh discipline. Freud hypothesized that the disorder is associated with difficulties in the anal stage of psychosexual development, generally around the age of 2 years, but various studies have failed to validate this theory.

**Diagnosis**

In interviews, patients with obsessive-compulsive personality disorder may have a stiff, formal, and rigid demeanor. Their affect is not blunted or flat but can be described as constricted. They lack spontaneity, and their mood is usually serious. Such patients may be anxious about not being in control of the interview. Their answers to questions are unusually detailed. The defense mechanisms they use are rationalization, isolation, intellectualization, reaction formation, and undoing. The DSM-5 diagnostic criteria for obsessive-compulsive personality disorder are listed in Table 22-10.

| Table 22-10 |
| **DSM-5 Diagnostic Criteria for Obsessive-Compulsive Personality Disorder** |
Clinical Features

Persons with obsessive-compulsive personality disorder are preoccupied with rules, regulations, orderliness, neatness, details, and the achievement of perfection. These traits account for the general constriction of the entire personality. They insist that rules be followed rigidly and cannot tolerate what they consider infractions. Accordingly, they lack flexibility and are intolerant. They are capable of prolonged work, provided it is routinized and does not require changes to which they cannot adapt.

Persons with obsessive-compulsive personality disorder have limited interpersonal skills. They are formal and serious and often lack a sense of humor. They alienate persons, are unable to compromise, and insist that others submit to their needs. They are eager to please those whom they see as more powerful than they are, however, and they carry out these persons’ wishes in an authoritarian manner. Because they fear making mistakes, they are indecisive and ruminate about making decisions. Although a stable marriage and occupational adequacy are common, persons with obsessive-compulsive personality disorder have few friends. Anything that threatens to upset their perceived stability or the routine of their lives can precipitate much anxiety otherwise bound up in the rituals that they impose on their lives and try to impose on others.

Differential Diagnosis

When recurrent obsessions or compulsions are present, obsessive-compulsive disorder should be noted. Perhaps the most difficult distinction is between outpatients with some obsessive-compulsive traits and those with obsessive-compulsive personality disorder. The diagnosis of personality disorder is reserved for those with significant impairments...
in their occupational or social effectiveness. In some cases, delusional disorder coexists with personality disorders and should be noted.

**Course and Prognosis**

The course of obsessive-compulsive personality disorder is variable and unpredictable. From time to time, persons may develop obsessions or compulsions in the course of their disorder. Some adolescents with obsessive-compulsive personality disorder evolve into warm, open, and loving adults; in others, the disorder can be either the harbinger of schizophrenia or—decades later and exacerbated by the aging process—major depressive disorder.

Persons with obsessive-compulsive personality disorder may flourish in positions demanding methodical, deductive, or detailed work, but they are vulnerable to unexpected changes, and their personal lives may remain barren. Depressive disorders, especially those of late onset, are common.

**Treatment**

**Psychotherapy.** Unlike patients with the other personality disorders, those with obsessive-compulsive personality disorder are often aware of their suffering, and they seek treatment on their own. Overtrained and oversocialized, these patients value free association and no-directive therapy highly. Treatment, however, is often long and complex, and countertransference problems are common.

Group therapy and behavior therapy occasionally offer certain advantages. In both contexts, it is easy to interrupt the patients in the midst of their maladaptive interactions or explanations. Preventing the completion of their habitual behavior raises patients’ anxiety and leaves them susceptible to learning new coping strategies. Patients can also receive direct rewards for change in group therapy, something less often possible in individual psychotherapies.

**Pharmacotherapy.** Clonazepam (Klonopin), a benzodiazepine with anticonvulsant use, has reduced symptoms in patients with severe obsessive-compulsive disorder. Whether it is of use in the personality disorder is unknown. Clomipramine (Anafranil) and such serotonergic agents as fluoxetine, usually at dosages of 60 to 80 mg a day, may be useful if obsessive-compulsive signs and symptoms break through. Nefazodone (Serzone) may benefit some patients.

**OTHER SPECIFIED PERSONALITY DISORDER**

In DSM-5, the category other specified personality disorder is reserved for disorders that do not fit into any of the personality disorder categories described above. Passive-aggressive personality and depressive personality are examples. A narrow spectrum of behavior or a particular trait—such as oppositionalism, sadism, or masochism—can also be classified in this category. A patient with features of more than one personality
disorder but without the complete criteria of any one disorder can be assigned this classification.

**Passive-Aggressive Personality**

Although no longer an official diagnosis, persons with this personality type are not uncommon. Persons with passive-aggressive personality are characterized by covert obstructionism, procrastination, stubbornness, and inefficiency. Such behavior is a manifestation of passively expressed underlying aggression.

**Epidemiology.** No data are available about epidemiology. Sex ratio, familial patterns, and prevalence have not been adequately studied.

**Clinical Features.** Patients with passive-aggressive personality characteristically procrastinate, resist demands for adequate performance, find excuses for delays, and find fault with those on whom they depend, yet they refuse to extricate themselves from the dependent relationships. They usually lack assertiveness and are not direct about their own needs and wishes. They fail to ask needed questions about what is expected of them and may become anxious when forced to succeed or when their usual defense of turning anger against themselves is removed.

In interpersonal relationships, these persons attempt to manipulate themselves into a position of dependence, but others often experience this passive, self-detrimental behavior as punitive and manipulative. Persons with this personality type expect others to do their errands and to carry out their routine responsibilities. Friends and clinicians may become enmeshed in trying to assuage the patients’ many claims of unjust treatment. The close relationships of persons with passive-aggressive personality, however, are rarely tranquil or happy. Because they are bound to their resentment more closely than to their satisfaction, they may never even formulate goals for finding enjoyment in life. Persons with passive-aggressive personality lack self-confidence and are typically pessimistic about the future.

**Differential Diagnosis.** Passive-aggressive personality must be differentiated from histrionic and borderline personality disorders. Passive-aggressive patients, however, are less flamboyant, dramatic, affective, and openly aggressive than those with histrionic and borderline personality disorders.

**Course and Prognosis.** In a follow-up study averaging 11 years of 100 inpatients diagnosed with passive-aggressive disorder, Ivor Small found that the primary diagnosis in 54 was passive-aggressive personality disorder; 18 were also alcohol abusers, and 30 could be clinically labeled as depressed. Of the 73 former patients located, 58 (79 percent) had persistent psychiatric difficulties, and 9 (12 percent) were considered symptom free. Most seemed irritable, anxious, and depressed; somatic complaints were numerous. Only 32 (44 percent) were employed full time as workers or homemakers. Although neglect of responsibility and suicide attempts were common, only one patient had committed suicide in the interim. Twenty-eight (38 percent) had been readmitted to a hospital, but only three had been diagnosed as having schizophrenia.
Patients with passive-aggressive personality who receive supportive psychotherapy have good outcomes, but psychotherapy for these patients has many pitfalls. Fulfilling their demands often supports their pathology, but refusing their demands rejects them. Therapy sessions, thus, can become a battleground on which a patient expresses feelings of resentment against a therapist on whom the patient wishes to become dependent. With these patients, clinicians must treat suicide gestures as any covert expression of anger and not as object loss in major depressive disorder. Therapists must point out the probable consequences of passive-aggressive behaviors as they occur. Such confrontations may be more helpful than a correct interpretation in changing patients’ behavior.

Antidepressants should be prescribed only when clinical indications of depression and the possibility of suicide exist. Otherwise, medication is not indicated.

Depressive Personality

Persons with depressive personality are characterized by lifelong traits that fall along the depressive spectrum. They are pessimistic, anhedonic, duty bound, self-doubting, and chronically unhappy. Melancholic personality was described by early 20th century European psychiatrists such as Ernst Kretschmer.

Epidemiology. No epidemiological data are currently available; however, depressive personality type seems to be common, to occur equally in men and women, and to occur in families in which depressive disorders are found.

Etiology. The cause of depressive personality is unknown, but the same factors involved in dysthymic disorder and major depressive disorder may be at work. Psychological theories involve early loss, poor parenting, punitive superegos, and extreme feelings of guilt. Biological theories involve the hypothalamic-pituitary-adrenal-thyroid axis, including the noradrenergic and serotonergic amine systems. Genetic predisposition, as indicated by Stella Chess’s studies of temperament, may also play a role.

Clinical Features. Patients with depressive personality feel little of the normal joy of living and are inclined to be lonely and solemn, gloomy, submissive, pessimistic, and self-deprecatory. They are prone to express regrets and feelings of inadequacy and hopelessness. They are often meticulous, perfectionistic, overconscientious, and preoccupied with work; feel responsibility keenly; and are easily discouraged under new conditions. They are fearful of disapproval; tend to suffer in silence; and perhaps to cry easily, although usually not in the presence of others. A tendency to hesitation, indecision, and caution betrays an inherent feeling of insecurity.

More recently, Hagop Akiskal described seven groups of depressive traits: (1) quiet, introverted, passive, and nonassertive; (2) gloomy, pessimistic, serious, and incapable of fun; (3) self-critical, self-reproachful, and self-derogatory; (4) skeptical, critical of others, and hard to please; (5) conscientious, responsible, and self-disciplined; (6) brooding and
given to worry; and (7) preoccupied with negative events, feelings of inadequacy, and personal shortcomings.

Patients with depressive personality complain of chronic feelings of unhappiness. They admit to low self-esteem and difficulty finding anything in their lives about which they are joyful, hopeful, or optimistic. They are self-critical and derogatory and are likely to denigrate their work, themselves, and their relationships with others. Their physiognomy often reflects their mood—poor posture, depressed facies, hoarse voice, and psychomotor retardation.

**Differential Diagnosis.** Dysthymic disorder is a mood disorder characterized by greater fluctuations in mood than occur in depressive personality. Dysthymic disorder is episodic, can occur at any time, and usually has a precipitating stressor. The depressive personality can be conceptualized as part of a spectrum of affective conditions in which dysthymic disorder and major depressive disorder are more severe variants. Patients with avoidant personality disorder are introverted and dependent, but they tend to be more anxious than depressed compared with persons with depressive personality.

**Course and Prognosis.** Persons with depressive personality may be at great risk for dysthymic disorder and major depressive disorder. In a study by Donald Klein and Gregory Mills, subjects with depressive personality exhibited significantly higher rates of current mood disorder, lifetime mood disorder, major depression, and dysthymia than subjects without depressive personality.

**Treatment.** Psychotherapy is the treatment of choice for depressive personality. Patients respond to insight-oriented psychotherapy, and because their reality testing is good, they can gain insight into the psychodynamics of their illness and appreciate its effects on their interpersonal relationships. Treatment is likely to be long term. Cognitive therapy helps patients understand the cognitive manifestations of their low self-esteem and pessimism. Group psychotherapy and interpersonal therapy are also useful. Some persons respond to self-help measures.

Psychopharmacological approaches include the use of antidepressant medications, especially such serotonergic agents as sertraline (Zoloft), 50 mg a day. Some patients respond to small dosages of psychostimulants, such as amphetamine, 5 to 15 mg a day. In all cases, psychopharmacological agents should be combined with psychotherapy to achieve maximum effects.

**Sadomasochistic Personality**

Some personality types are characterized by elements of sadism or masochism or a combination of both. Sadomasochistic personality is listed here because it is of major clinical and historical interest in psychiatry. It is not an official diagnostic category in DSM-5, but it can be diagnosed as personality disorder not otherwise classified.

Sadism is the desire to cause others pain by being either sexually abusive or generally physically or psychologically abusive. It is named for the Marquis de Sade, a late 18th century writer of erotica, describing persons who experienced sexual pleasure while inflicting pain on others. Freud believed that sadists ward off castration anxiety and are able to achieve sexual pleasure only when they can do to others what they fear will be done to them.

Masochism, named for Leopold von Sacher-Masoch, a 19th century German novelist, is the achievement of sexual gratification by inflicting pain on the self. So-called moral masochists generally seek humiliation and failure rather than
physical pain. Freud believed that masochists’ ability to achieve orgasm is disturbed by anxiety and guilt feelings about sex, which are alleviated by suffering and punishment.

Clinical observations indicate that elements of both sadistic and masochistic behavior are usually present in the same person. Treatment with insight-oriented psychotherapy, including psychoanalysis, has been effective in some cases. As a result of therapy, patients become aware of the need for self-punishment secondary to excessive unconscious guilt and come to recognize their repressed aggressive impulses, which originate in early childhood.

**Sadistic Personality**

Sadistic personality is not included in DSM-5, but it still appears in the literature and may be of descriptive use. Beginning in early adulthood, persons with sadistic personality show a pervasive pattern of cruel, demeaning, and aggressive behavior that is directed toward others. Physical cruelty or violence is used to inflict pain on others, not to achieve another goal, such as mugging a person to steal. Persons with sadistic personality like to humiliate or demean persons in front of others and have usually treated or disciplined persons uncommonly harshly, especially children. In general, persons with sadistic personality are fascinated by violence, weapons, injury, or torture. To be included in this category, such persons cannot be motivated solely by the desire to derive sexual arousal from their behavior; if they are so motivated, the paraphilia of sexual sadism should be diagnosed.

**PERSONALITY CHANGE DUE TO A GENERAL MEDICAL CONDITION**

Personality change due to a general medical condition is a significant occurrence. ICD-10 includes the category personality and behavioral disorders due to brain disease, damage, and dysfunction, which includes organic personality disorder, postencephalitic syndrome, and postconcussional syndrome. Personality change due to a general medical condition is characterized by a marked change in personality style and traits from a previous level of functioning. Patients must show evidence of a causative organic factor antedating the onset of the personality change.

**Etiology**

Structural damage to the brain is usually the cause of the personality change, and head trauma is probably the most common cause. Cerebral neoplasms and vascular accidents, particularly of the temporal and frontal lobes, are also common causes. The conditions most often associated with personality change are listed in Table 22-11.

Diagnosis and Clinical Features

A change in personality from previous patterns of behavior or an exacerbation of previous personality characteristics is notable. Impaired control of the expression of emotions and impulses is a cardinal feature. Emotions are characteristically labile and shallow, although euphoria or apathy may be prominent. The euphoria may mimic hypomania, but true elation is absent, and patients may admit to not really feeling happy. There is a hollow and silly ring to their excitement and facile jocularity, particularly when the frontal lobes are involved. Also associated with damage to the frontal lobes, the so-called frontal lobe syndrome, consists of prominent indifference and apathy, characterized by a lack of concern for events in the immediate environment. Temper outbursts, which can occur with little or no provocation, especially after alcohol ingestion, can result in violent behavior. The expression of impulses may be manifested by inappropriate jokes; a coarse manner; improper sexual advances; and antisocial conduct resulting in conflicts with the law, such as assaults on others, sexual misdemeanors, and shoplifting. Foresight and the ability to anticipate the social or legal consequences of actions are typically diminished. Persons with temporal lobe epilepsy characteristically show humorlessness, hypergraphia, hyperreligiosity, and marked aggressiveness during seizures.

Persons with personality change due to a general medical condition have a clear sensorium. Mild disorders of cognitive function often coexist but do not amount to intellectual deterioration. Patients may be inattentive, which may account for disorders of recent memory. With some prodding, however, patients are likely to recall what they claim to have forgotten. The diagnosis should be suspected in patients who show marked changes in behavior or personality involving emotional lability and impaired impulse control, who have no history of mental disorder, and whose personality changes occur abruptly or over a relatively brief time.

Anabolic Steroids. An increasing number of high school and college athletes and bodybuilders are using anabolic steroids as a shortcut to maximize physical development. Anabolic steroids include oxymetholone (Anadrol), somatropin (Humatrope), stanozolol (Winstrol), and testosterone.

It is unclear whether a personality change caused by steroid abuse is better diagnosed as personality change due to a general medical condition or as one of the other (or unknown) substance use disorders. It is mentioned here because anabolic steroids can cause persistent alterations of personality and behavior. Anabolic steroid abuse is discussed in Section 12.13.

Differential Diagnosis

Dementia involves global deterioration in intellectual and behavioral capacities, of which personality change is just one category. A personality change may herald a cognitive disorder that eventually will evolve into dementia. In these cases, as deterioration begins to encompass significant memory and cognitive deficits, the
diagnosis of the disorder changes from personality change caused by a general medical condition to dementia. In differentiating the specific syndrome from other disorders in which personality change may occur—such as schizophrenia, delusional disorder, mood disorders, and impulse control disorders—physicians must consider the most important factor, the presence in personality change disorder of a specific organic causative factor.

**Course and Prognosis**

Both the course and the prognosis of personality change due to a general medical condition depend on its cause. If the disorder results from structural damage to the brain, the disorder tends to persist. The disorder may follow a period of coma and delirium in cases of head trauma or vascular accident and may be permanent. The personality change can evolve into dementia in cases of brain tumor, multiple sclerosis, and Huntington’s disease. Personality changes produced by chronic intoxication, medical illness, or drug therapy (such as levodopa [Larodopa] for parkinsonism) may be reversed if the underlying cause is treated. Some patients require custodial care or at least close supervision to meet their basic needs, avoid repeated conflicts with the law, and protect themselves and their families from the hostility of others and from destitution resulting from impulsive and ill-considered actions.

**Treatment**

Management of personality change disorder involves treatment of the underlying organic condition when possible. Psychopharmacological treatment of specific symptoms may be indicated in some cases, such as imipramine or fluoxetine for depression.

Patients with severe cognitive impairment or weakened behavioral controls may need counseling to help avoid difficulties at work or to prevent social embarrassment. As a rule, patients’ families need emotional support and concrete advice on how to help minimize patients’ undesirable conduct. Alcohol should be avoided, and social engagements should be curtailed when patients tend to act in a grossly offensive manner.

**PSYCHOBIOLOGICAL MODEL OF TREATMENT**

The psychobiological model of treatment combines psychotherapy and pharmacotherapy and is based on the established structural, clinical, and postulated neurochemical characteristics of temperament and character. Pharmacotherapy and psychotherapy can be systematically matched to the personality structure and stage of character development of each patient—clearly a unique advantage over other available approaches.

The newest development is treating personality disorders pharmacologically. Target symptoms are identified, and particular drugs with known effects on personality traits (e.g., harm avoidance) are used. Table 22-12 summarizes drug choices for various target
In his book, Listening to Prozac, Peter Kramer described dramatic personality changes when serotonin levels are raised by fluoxetine administration, such as decreased sensitivity to rejection, increased assertiveness, improved self-esteem, and the ability to tolerate stress. These changes in personality traits occur in patients with a wide range of psychiatric conditions as well as in persons without diagnosable mental disorders. Using medications to treat specific traits in a person who is otherwise normal (i.e., does not meet the criteria for a full-blown personality disorder) is controversial. It has been called “cosmetic psychopharmacology” by its critics.

### Temperament

Temperament refers to the body’s biases in the modulation of conditioned behavioral...
responses to prescriptive physical stimuli. Behavioral conditioning (i.e., procedural learning) involves presemantic sensations that elicit basic emotions, such as fear or anger, independent of conscious recognition, descriptive observation, reflection, or reasoning. Pioneering work by A. Thomas and S. Chess conceptualized temperament as the stylistic component (“how”) of behavior, as differentiated from the motivation (“why”) and the content (“what”) of behavior. Modern concepts of temperament, however, emphasize its emotional, motivational, and adaptive aspects. Specifically, four major temperament traits have been identified and subjected to extensive neurobiological, psychosocial, and clinical investigation: harm avoidance, novelty seeking, reward dependence, and persistence. It is remarkable that this four-factor model of temperament can, in retrospect, be seen as a modern interpretation of the ancient four temperaments: Individuals differ in the degree to which they are melancholic (harm avoidance), choleric (novelty seeking), sanguine (reward dependence), and phlegmatic (persistence). However, the four temperaments are now understood to be genetically independent dimensions that occur in all possible combinations within the same individual rather than as mutually exclusive categories.

**Biological Character Traits.** Four character traits have been described, each with certain neurochemical and neurophysiological substrates. They share a common source of covariation that is strong and invariant regardless of changes in the environment and past experience. Table 22-13 summarizes contrasting sets of behaviors that distinguish extreme scorers on the four dimensions of temperament. Note that each extreme of these dimensions has specific adaptive advantages and disadvantages, so that neither high nor low scores inherently mean better adaptation. Each of the four temperament dimensions has unique genetic determinants according to family and twin studies, as well as studies of genetic associations with specific DNA markers. Some workers postulate specific genes for some traits, such as a novelty-seeking gene.

<table>
<thead>
<tr>
<th>Table 22-13</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Descriptors of Individuals Who Score High or Low on the Four Temperament Dimensions</strong></td>
</tr>
</tbody>
</table>
HARM AVOIDANCE. Harm avoidance involves a heritable bias in the inhibition of behavior in response to signals of punishment and nonreward. High harm avoidance is observed as fear of uncertainty, social inhibition, shyness with strangers, rapid fatigability, and pessimistic worry in anticipation of problems even in situations that do not worry other persons. Persons low in harm avoidance are carefree, courageous, energetic, outgoing, and optimistic even in situations that worry most persons.

The psychobiology of harm avoidance is complex. Benzodiazepines disinhibit avoidance by γ-aminobutyric acid (GABA)-ergic inhibition of serotonergic neurons originating in the dorsal raphe nuclei.

Positron emission tomography (PET) at the National Institute of Mental Health (NIMH) with $^{[18]}\text{F}$-deoxyglucose (FDG) in 31 healthy adult volunteers during a simple, continuous performance task showed that harm avoidance was associated with increased activity in the anterior paralimbic circuit, specifically the right amygdala and insula, the right orbitofrontal cortex, and the left medial prefrontal cortex.

High GABA concentrations in plasma have also been correlated with low harm avoidance. Plasma GABA concentration has also been correlated with other measures of anxiety susceptibility, and it correlates highly with GABA concentration in the brain. Finally, a gene on chromosome 17q12 that regulates the expression of the serotonin transporter accounts for 4 to 9 percent of the total variance in harm avoidance. These findings support a role for both GABA and serotonergic projections from the dorsal raphe underlying individual differences in behavioral inhibition as measured by harm avoidance. Persons given serotonin drugs show decreased harm avoidance behavior.

NOVELTY SEEKING. Novelty seeking reflects a heritable bias in the initiation or activation of appetitive approach in response to novelty, approach to signals of reward, active avoidance of conditioned signals of punishment, and escape from unconditioned punishment (all of which are hypothesized to covary as part of one heritable system of learning). Novelty seeking is observed as exploratory activity in response to novelty, impulsiveness, extravagance in approach to cues of reward, and active avoidance of
frustration. Individuals high in novelty seeking are quick tempered, curious, easily bored, impulsive, extravagant, and disorderly. Persons low in novelty seeking are slow tempered, uninquiring, stoical, reflective, frugal, reserved, tolerant of monotony, and orderly.

Dopaminergic projections have a crucial role in novelty seeking. Novelty seeking involves increased reuptake of dopamine at presynaptic terminals, thereby requiring frequent stimulation to maintain optimal levels of postsynaptic dopaminergic stimulation. Novelty seeking leads to various pleasure-seeking behaviors, including cigarette smoking, which may explain the frequent observation of low platelet MAO type B (MAO_B) activity because cigarette smoking inhibits MAO_B activity in platelets and brain.

Studies of genes involved in dopamine neurotransmission, such as the dopamine transporter gene (DAT1) and the type 4 dopamine receptor gene (DRD4), have provided evidence of association with novelty seeking or risk-taking behavior.

REWARD DEPENDENCE. Reward dependence reflects maintenance of behavior in response to cues of social reward. Individuals high in reward dependence are tender hearted, sensitive, socially dependent, and sociable. Individuals low in reward dependence are practical, tough minded, cold, socially insensitive, irresolute, and indifferent if alone.

Noradrenergic projections from the locus ceruleus and serotonergic projections from the median raphe are thought to influence such reward conditioning. High reward dependence is associated with increased activity in the thalamus. The 3-methoxy-4-hydroxyphenylglycol (MHPG) concentration is low in persons with high reward dependence.

PERSISTENCE. Persistence reflects maintenance of behavior despite frustration, fatigue, and intermittent reinforcement. Highly persistent persons are hard-working, perseverant, and ambitious overachievers who tend to intensify their effort in response to anticipated rewards and view frustration and fatigue as personal challenges. Individuals low in persistence are indolent, inactive, unstable, and erratic; they tend to give up easily when faced with frustration, rarely strive for higher accomplishments, and manifest little perseverance even in response to intermittent reward.

Recent work in rodents related the integrity of the partial reinforcement extinction effect to hippocampal connections and glutamate metabolism. Persistence may be enhanced by psychostimulants.

Psychobiology of Temperament. Temperament traits of harm avoidance, novelty seeking, reward dependence, and persistence are defined as heritable differences underlying automatic responses to danger, novelty, social approval, and intermittent reward, respectively. The component traits ("facets") for each of the four temperament dimensions have distinct learning characteristics and correlate more strongly with one another than with other components of temperament. The most comprehensive neurobiological model of learning in animals that has been
systematically related to the structure of human temperament is summarized in Table 22-14. This model distinguishes four dissociable brain systems for behavioral inhibition (harm avoidance), behavioral activation (novelty seeking), social attachment (reward dependence), and partial reinforcement (persistence).

CS, conditioned stimulus; GABA, γ-aminobutyric acid; UCS, unconditioned stimulus. Adapted from Cloninger CR. A systematic method for clinical description and classification of personality variables. *Arch Gen Psychiatry.* 1987;44:573.

Individual differences in temperament and basic emotions modify the processing of sensory information and shape early learning characteristics, especially associative conditioning of unconscious behavior responses. Temperament is conceptualized in terms of heritable biases in emotionality and learning that underlie the acquisition of emotion-based, automatic behavioral traits and habits observable early in life and relatively stable over an individual’s lifespan.

Each of the four major dimensions is a normally distributed quantitative trait, moderately heritable, observable early in childhood, relatively stable in time, and moderately predictive of adolescent and adult behavior. The four dimensions have been shown to be genetically homogeneous and independently inherited from one another in large, independent twin studies in the United States, Australia, and Japan. Temperamental differences, which are not very stable initially, tend to stabilize during the second and third years of life. Accordingly, ratings of these four temperament traits at age 10 to 11 years were moderately predictive of personality traits at ages 15, 18, and 27 years in a large sample of Swedish children.

The four dimensions have been repeatedly shown to be universal across different cultures, ethnic groups, and political systems on every inhabited continent. In summary, these aspects of personality are called temperament because they are heritable, manifest early in life, are developmentally stable, and are consistent in different cultures. Temperament traits are similar to crystallized intelligence in that they do not show the rapid changes with increasing age or across birth cohorts that are observed for fluid intelligence and character traits.
REFERENCES
23.1 Suicide

*Suicide* is derived from the Latin word for “self-murder.” It is a fatal act that represents the person’s wish to die. There is a range, however, between thinking about suicide and acting it out. Some plan for days, weeks, or even years before acting, while others take their lives seemingly on impulse without premeditation. Lost in the definition are intentional misclassifications of the cause of death, accidents of undetermined cause, and so-called chronic suicide (e.g., deaths through alcohol and substance abuse and consciously poor adherence to medical regimens for addiction, obesity, and hypertension). For other terms in the literature on suicide, see Table 23.1-1.

In psychiatry, suicide is the primary emergency, with homicide and failure to diagnose an underlying potentially fatal illness representing other, less common psychiatric emergencies. Suicide is to the psychiatrist as cancer is to the internist—the psychiatrist may provide optimal care, yet the patient may die by suicide nonetheless. Thus, suicide is impossible to predict, but numerous clues can be seen. There are also some generally accepted standards of care that facilitate risk reduction, as well as lessen the likelihood of successful litigation, should a patient death occur and a lawsuit be filed. Suicide also needs to be considered in terms of the devastating legacy that it leaves for those who have survived a loved one’s suicide, the impact it has on the treating physician, and the ramifications for the clinicians who cared for the decedents. Perhaps the most important
concept regarding suicide is that it is almost always the result of mental illness, usually depression, and is amenable to psychological and pharmacological treatment.

**EPIDEMIOLOGY**

There are over 35,000 deaths per year (approximately 100 per day) in the United States attributed to suicide. This is in contrast to approximately 20,000 deaths annually from homicide. It is estimated that there is a 25 to 1 ratio between suicide attempts and completed suicides. Although significant shifts were seen in the suicide death rates for certain subpopulations during the past century (e.g., increase adolescent and decreased elderly rates), the rate remains fairly constant, averaging about 12 per 100,000 through the 20th century and into the first decade of the 21st century. Suicide is currently ranked the tenth overall cause of death in the United States, after heart disease, cancer, chronic lower respiratory diseases, cerebrovascular diseases, accidents, Alzheimer’s disease, diabetes, influenza and pneumonia, and kidney disease.

Suicide rates in the United States are the midpoint of the rates for industrialized countries. Internationally, suicide rates range from highs of more than 25 per 100,000 persons in Lithuania, South Korea, Sri Lanka, Russia, Belarus, and Guyana to fewer than 10 per 100,000 in Portugal, the Netherlands, Australia, Spain, South Africa, Italy, Egypt, and others.

A state-by-state analysis of suicides in the past decade revealed that New Jersey had the nation’s lowest suicide rate for both sexes and Montana had the nation’s highest rate. Montana and Wyoming had the highest rates for men, and Alaska and Idaho had the highest rates for women. The prime suicide site in the world is the Golden Gate Bridge in San Francisco, with 1,600 suicides committed there since the bridge opened in 1937.

**Risk Factors**

**Gender Differences.** Men commit suicide more than four times as often as women, regardless of age or race, in the United States—despite the fact that women attempt suicide or have suicidal thoughts three times as often as men. Although this disparity remains unclear, it may be related to the methods used. Men are more likely than women to commit suicide using firearms, hanging, or jumping from high places. Women, on the other hand, more commonly take an overdose of psychoactive substances or poison. The use of firearms among women, however, is increasing. In states with gun control laws, the use of firearms has decreased as a method of suicide. Globally, the most common method of suicide is hanging.

**Age.** For all groups, suicide is rare before puberty. Suicide rates increase with age and underscore the significance of the midlife crisis. Among men, suicides peak after age 45; among women, the greatest number of completed suicides occurs after age 55. Rates of 29 per 100,000 population occur in men age 65 or older. Older persons attempt
suicide less often than younger persons, but are more often successful. Although they represent only 13 percent of the total population, older persons account for 16 percent of suicides.

The suicide rate, however, is rising among young persons. Suicide is the third leading cause of death in those aged 15 to 24 years, after accidents and homicides. Attempted suicides in this age group number between 1 million and 2 million annually. Most suicides now are among those aged 35 to 64.

**Race.** Suicide rates among white men and women are approximately two to three times as high as for African American men and women across the life cycle. Among young persons who live in inner cities and certain Native American and Alaskan Native groups, suicide rates have greatly exceeded the national rate. Suicide rates among immigrants are higher than those in the native-born population.

**Religion.** Historically, Protestants and Jews in the United States have had higher suicide rates than Catholics. Muslims have much lower rates. The degree of orthodoxy and integration may be a more accurate measure of risk in this category than simple institutional religious affiliation.

**Marital Status.** Marriage lessens the risk of suicide significantly, especially if there are children in the home. Single, never-married persons register an overall rate nearly double that of married persons. Divorce increases suicide risk, with divorced men three times more likely to kill themselves as divorced women. Widows and widowers also have high rates. Suicide occurs more frequently than usual in persons who are socially isolated and have a family history of suicide (attempted or real). Persons who commit so-called anniversary suicides take their lives on the day a member of their family did. Homosexual men and women appear to have higher rates of suicide than heterosexuals.

**Occupation.** The higher the person’s social status, the greater the risk of suicide, but a drop in social status also increases the risk. Work, in general, protects against suicide. Among occupational rankings, professionals, particularly physicians, have traditionally been considered to be at greatest risk. Other high-risk occupations include law enforcement, dentists, artists, mechanics, lawyers, and insurance agents. Suicide is higher among the unemployed than among employed persons. The suicide rates increase during economic recessions and depressions and decrease during times of high employment and during wars.

**Physician Suicides.** The weight of current evidence supports the conclusion that both male and female physicians in the United States have elevated rates of suicide. It is estimated that approximately 400 physicians commit suicide each year in the United States. United Kingdom and Scandinavian data show that the suicide rate for male physicians is two to three times that found in the general male population of the same age. Female physicians have a higher risk of suicide than other women. In the United States, the annual suicide rate for female physicians is about 41 per 100,000, compared
with 12 per 100,000 among all white women over 25 years of age. Studies show that physicians who commit suicide have a mental disorder, most often depressive disorder, substance dependence, or both. Both male and female physicians commit suicide significantly more often by substance overdoses and less often by firearms than persons in the general population; drug availability and knowledge about toxicity are important factors in physician suicides. Among physicians, psychiatrists are considered to be at greatest risk, followed by ophthalmologists and anesthesiologists, but all specialties are vulnerable.

**Climate.** No significant seasonal correlation with suicide has been found. Suicides increase slightly in spring and fall but, contrary to popular belief, not during December and holiday periods.

**Physical Health.** The relation of physical health and illness to suicide is significant. Previous medical care appears to be a positively correlated risk indicator of suicide: About one third of all persons who commit suicide have had medical attention within 6 months of death, and a physical illness is estimated to be an important contributing factor in about half of all suicides.

Factors associated with illness that contribute to both suicides and suicide attempts are loss of mobility, especially when physical activity is important to occupation or recreation; disfigurement, particularly among women; and chronic, intractable pain. Patients on hemodialysis are at high risk. In addition to the direct effects of illness, the secondary effects—for example, disruption of relationships and loss of occupational status—are prognostic factors.

Certain drugs can produce depression, which may lead to suicide in some cases. Among these drugs are reserpine (Serpasil), corticosteroids, antihypertensives, and some anticancer agents. Alcohol-related illnesses, such as cirrhosis, are associated with higher suicide rates.

**Mental Illness.** Almost 95 percent of all persons who commit or attempt suicide have a diagnosed mental disorder. Depressive disorders account for 80 percent of this figure, schizophrenia accounts for 10 percent, and dementia or delirium for 5 percent. Among all persons with mental disorders, 25 percent are also alcohol dependent and have dual diagnoses. Persons with delusional depression are at highest risk of suicide. A history of impulsive behavior or violent acts increases the risk of suicide as does previous psychiatric hospitalization for any reason. Among adults who commit suicide, significant differences between young and old exist for both psychiatric diagnoses and antecedent stressors. Diagnoses of substance abuse and antisocial personality disorder occurred most often among suicides in persons less than 30 years of age and diagnoses of mood disorders and cognitive disorders most often among suicides in those age 30 and above. Stressors associated with suicide in those under 30 were separation, rejection, unemployment, and legal troubles; illness stressors most often occurred among suicide victims over age 30.

**Psychiatric Patients.** Psychiatric patients’ risk for suicide is 3 to 12 times that of nonpatients. The degree of risk varies, depending on age, sex, diagnosis, and inpatient
or outpatient status. Male and female psychiatric patients who have at some time been inpatients have five and ten times higher suicide risks, respectively, than their counterparts in the general population. For male and female outpatients who have never been admitted to a hospital for psychiatric treatment, the suicide risks are three and four times greater, respectively, than those of their counterparts in the general population. The higher suicide risk for psychiatric patients who have been inpatients reflects that patients with severe mental disorders tend to be hospitalized—for example, patients with depressive disorder who require electroconvulsive therapy (ECT). The psychiatric diagnosis with greatest risk of suicide in both sexes is a mood disorder.

Those in the general population who commit suicide tend to be middle aged or older, but studies increasingly report that psychiatric patients who commit suicide tend to be relatively young. In one study, the mean age of male suicides was 29.5 years and that of women 38.4 years. The relative youthfulness in these suicide cases was partly attributed to two early-onset, chronic mental disorders—schizophrenia and recurrent major depressive disorder—which account for just over half of these suicides, and so reflects an age and diagnostic pattern found in most studies of psychiatric patient suicides.

A small, but significant, percentage of psychiatric patients who commit suicide do so while they are inpatients. Most of these do not kill themselves in the psychiatric ward itself, but on the hospital grounds, while on a pass or weekend leave, or when absent without leave. For both sexes, the suicide risk is highest in the first week of the psychiatric admission; after 3 to 5 weeks, inpatients have the same risk as the general population. Times of staff rotation, particularly of the psychiatric residents, are periods associated with inpatient suicides. Epidemics of inpatient suicides tend to be associated with periods of ideological change on the ward, staff disorganization, and staff demoralization.

The period after discharge from the hospital is also a time of increased suicide risk. A follow-up study of 5,000 patients discharged from an Iowa psychiatric hospital showed that in the first 3 months after discharge, the rate of suicide for female patients was 275 times that of all Iowa women; the rate of suicide for male patients was 70 times that of all Iowa men. Studies show that one third or more of depressed patients who commit suicide do so within 6 months of leaving a hospital; presumably they have relapsed.

The main risk groups are patients with depressive disorders, schizophrenia, and substance abuse and patients who make repeated visits to the emergency room. Patients, especially those with panic disorder, who frequent emergency services, also have an increased suicide risk. Thus, mental health professionals working in emergency services must be well trained in assessing suicidal risk and making appropriate dispositions. They must also be aware of the need to contact patients at risk who fail to keep follow-up appointments.

**DEPRESSIVE DISORDERS.** Mood disorders are the ones most closely linked to suicide. Approximately 60 to 70 percent of suicide victims suffered a significant depression at the time of their deaths. The lifetime risk of death by suicide among individuals with bipolar disorder is approximately 15 to 20 percent, and suicide is more likely during depressed states rather than manic states.

More patients with depressive disorders commit suicide early in the illness rather than later; more depressed men than women commit suicide; and the chance of depressed persons’ killing themselves increases if they are single, separated, divorced, widowed, or recently bereaved. Patients with depressive disorder in the community who commit suicide tend to be middle aged or older.

Social isolation enhances suicidal tendencies among depressed patients. This finding is in accord with the data from epidemiological studies showing that persons who commit suicide may be poorly integrated into society. Suicide among
depressed patients is likely at the onset or the end of a depressive episode. As with other psychiatric patients, the months after discharge from a hospital are a time of high risk.

Regarding outpatient treatment, most depressed suicidal patients had a history of therapy; however, less than half were receiving psychiatric treatment at the time of suicide. Of those who were in treatment, studies have shown that treatment was less than adequate. For example, most patients who received antidepressants were prescribed subtherapeutic doses of the medication.

**SCHIZOPHRENIA.** The suicide risk is high among patients with schizophrenia: Up to 10 percent die by committing suicide. In the United States, an estimated 4,000 patients with schizophrenia commit suicide each year. The onset of schizophrenia is typically in adolescence or early adulthood, and most of these patients who commit suicide do so during the first few years of their illness; therefore, those patients with schizophrenia who commit suicide are young.

Thus, the risk factors for suicide among patients with schizophrenia are young age, male gender, single marital status, a previous suicide attempt, a vulnerability to depressive symptoms, and a recent discharge from a hospital. Having three or four hospitalizations during their 20s probably undermines the social, occupational, and sexual adjustment of possibly suicidal patients with schizophrenia. Consequently, potential suicide victims are likely to be male, unmarried, unemployed, socially isolated, and living alone—perhaps in a single room. After discharge from their last hospitalization, they may experience a new adversity or return to ongoing difficulties. As a result, they become dejected, experience feelings of helplessness and hopelessness, reach a depressed state, and have, and eventually act on, suicidal ideas. Only a small percentage committed suicide because of hallucinated instructions or a need to escape persecutory delusions. Up to 50 percent of suicides among patients with schizophrenia occur during the first few weeks and months after discharge from a hospital; only a minority commit suicide while inpatients.

**ALCOHOL DEPENDENCE.** Up to 15 percent of all alcohol-dependent persons commit suicide. The suicide rate for those who are alcoholic is estimated to be about 270 per 100,000 annually; in the United States, between 7,000 and 13,000 alcohol-dependent persons commit suicide each year.

About 80 percent of all alcohol-dependent suicide victims are male, a percentage that largely reflects the sex ratio for alcohol dependence. Alcohol-dependent suicide victims tend to be white, middle aged, unmarried, friendless, socially isolated, and currently drinking. Up to 40 percent have made a previous suicide attempt. Up to 40 percent of all suicides by persons who are alcohol dependent occur within a year of the patient's last hospitalization; older alcohol-dependent patients are at particular risk during the postdischarge period.

Studies show that many alcohol-dependent patients who eventually commit suicide are rated depressed during hospitalization and up to two thirds are assessed as having mood disorder symptoms during the period in which they commit suicide. As many as 50 percent of all alcohol-dependent suicide victims have experienced the loss of a close, affectionate relationship during the previous year. Such interpersonal losses and other types of undesirable life events are probably brought about by the alcohol dependence and contribute to the development of the mood disorder symptoms, which are often present in the weeks and months before the suicide.

The largest group of male alcohol-dependent patients is composed of those with an associated antisocial personality disorder. Studies show that such patients are particularly likely to attempt suicide; to abuse other substances; to exhibit
impulsive, aggressive, and criminal behaviors; and to be found among alcohol-dependent suicide victims.

**OTHER SUBSTANCE DEPENDENCE.** Studies in various countries have found an increased suicide risk among those who abuse substances. The suicide rate for persons who are heroin dependent is about 20 times the rate for the general population. Adolescent girls who use intravenous substances also have a high suicide rate. The availability of a lethal amount of substances, intravenous use, associated antisocial personality disorder, a chaotic lifestyle, and impulsivity are some of the factors that predispose substance-dependent persons to suicidal behavior, particularly when they are dysphoric, depressed, or intoxicated.

**PERSONALITY DISORDERS.** A high proportion of those who commit suicide have various associated personality difficulties or disorders. Having a personality disorder may be a determinant of suicidal behavior in several ways: by predisposing to major mental disorders such as depressive disorders or alcohol dependence; by leading to difficulties in relationships and social adjustment; by precipitating undesirable life events; by impairing the ability to cope with a mental or physical disorder; and by drawing persons into conflicts with those around them, including family members, physicians, and hospital staff members.

An estimated 5 percent of patients with antisocial personality disorder commit suicide. Suicide is three times more common among prisoners than among the general population. More than one third of prisoner suicides have had past psychiatric treatment, and half have made a previous suicide threat or attempt, often in the previous 6 months.

**ANXIETY DISORDER.** Uncompleted suicide attempts are made by almost 20 percent of patients with a panic disorder and social phobia. If depression is an associated feature, however, the risk of completed suicide rises.

**Previous Suicidal Behavior.** A past suicide attempt is perhaps the best indicator that a patient is at increased risk of suicide. Studies show that about 40 percent of depressed patients who commit suicide have made a previous attempt. The risk of a second suicide attempt is highest within 3 months of the first attempt. The relation between a mood disorder, completed suicide, and attempts at suicide is shown in Figure 23.1-1.
Depression is associated with both completed suicide and serious attempts at suicide. The clinical feature most often associated with the seriousness of the intent to die is a diagnosis of a depressive disorder. This is shown by studies that relate the clinical characteristics of suicidal patients with various measures of the medical seriousness of the attempt or of the intent to die. Also, intent-to-die scores correlate significantly with both suicide risk scores and the number and severity of depressive symptoms. Patients having high suicide intent are more often male, older, single or separated, and living alone than those with low intent. In other words, depressed patients who seriously attempt suicide more closely resemble suicide victims than they do suicide attempters.

**ETIOLOGY**

**Sociological Factors**

**Durkheim’s Theory.** The first major contribution to the study of the social and cultural influences on suicide was made at the end of the 19th century by the French sociologist Emile Durkheim. In an attempt to explain statistical patterns, Durkheim divided suicides into three social categories: egoistic, altruistic, and anomic. Egoistic suicide applies to those who are not strongly integrated into any social group. The lack of family integration explains why unmarried persons are more vulnerable to suicide than married ones and why couples with children are the best protected group. Rural communities have more social integration than urban areas and, thus, fewer suicides. Protestantism is a less cohesive religion than Roman Catholicism, and so Protestants have a higher suicide rate than Catholics.

Altruistic suicide applies to those susceptible to suicide stemming from their excessive integration into a group, with suicide being the outgrowth of the integration—for example, a Japanese soldier who sacrifices his life in battle. Anomic suicide applies to persons whose integration into society is disturbed so that they cannot follow customary norms of behavior. Anomie explains why a drastic change in economic situation makes persons more vulnerable than they were before their change in fortune. In Durkheim’s
Psychological Factors

Freud’s Theory. Sigmund Freud offered the first important psychological insight into suicide. He described only one patient who made a suicide attempt, but he saw many depressed patients. In his paper “Mourning and Melancholia,” Freud stated his belief that suicide represents aggression turned inward against an introjected, ambivalently cathected love object. Freud doubted that there would be a suicide without an earlier repressed desire to kill someone else.

Menninger’s Theory. Building on Freud’s ideas, Karl Menninger, in Man against Himself, conceived of suicide as inverted homicide because of a patient’s anger toward another person. This retroflexed murder is either turned inward or used as an excuse for punishment. He also described a self-directed death instinct (Freud’s concept of Thanatos) plus three components of hostility in suicide: the wish to kill, the wish to be killed, and the wish to die.

Recent Theories. Contemporary suicidologists are not persuaded that a specific psychodynamic or personality structure is associated with suicide. They believe that much can be learned about the psychodynamics of suicidal patients from their fantasies about what would happen and what the consequences would be if they commit suicide. Such fantasies often include wishes for revenge, power, control, or punishment; atonement, sacrifice, or restitution; escape or sleep; rescue, rebirth, reunion with the dead; or a new life. The suicidal patients most likely to act out suicidal fantasies may have lost a love object or received a narcissistic injury, may experience overwhelming affects like rage and guilt, or may identify with a suicide victim. Group dynamics underlie mass suicides such as those at Masada, at Jonestown, and by the Heaven’s Gate cult.

Depressed persons may attempt suicide just as they appear to be recovering from their depression. A suicide attempt can cause a long-standing depression to disappear, especially if it fulfills a patient’s need for punishment. Of equal relevance, many suicidal patients use a preoccupation with suicide as a way of fighting off intolerable depression and a sense of hopelessness. A study by Aaron Beck showed that hopelessness was one of the most accurate indicators of long-term suicidal risk.

Biological Factors. Diminished central serotonin plays a role in suicidal behavior. A group at the Karolinska Institute in Sweden first noted that low concentrations of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in the lumbar cerebrospinal fluid (CSF) were associated with suicidal behavior. This finding has been replicated many times and in different diagnostic groups. Postmortem neurochemical studies have reported modest decreases in serotonin itself or 5-HIAA in either the brainstem or the
frontal cortex of suicide victims. Postmortem receptor studies have reported significant changes in presynaptic and postsynaptic serotonin binding sites in suicide victims. Together, these CSF, neurochemical, and receptor studies support the hypothesis that reduced central serotonin is associated with suicide. Recent studies also report some changes in the noradrenergic system of suicide victims.

Low concentrations of 5-HIAA in CSF also predict future suicidal behavior. For example, the Karolinska group examined completed suicide in a sample of 92 depressed patients who had attempted suicide. They found that 8 of the 11 patients who committed suicide within 1 year belonged to the subgroup with below-median concentrations of 5-HIAA in CSF. The suicide risk in that subgroup was 17 percent, compared with 7 percent among those with above-median concentrations of 5-HIAA in CSF (Fig. 23.1-2). Also, the cumulative number of patient-months survived during the first year after attempted suicide was significantly lower in the subgroup with low 5-HIAA concentrations. The Karolinska group concluded that low 5-HIAA concentrations in CSF predict short-range suicide risk in the high-risk group of depressed patients who have attempted suicide. Low 5-HIAA concentrations in CSF have also been demonstrated in adolescents who kill themselves.

**FIGURE 23.1-2**
Cumulative suicide risk during first year after attempted suicide in patients with low versus high cerebrospinal fluid (CSF) concentrations of 5-hydroxyindoleacetic acid (5-HIAA). Filled circles indicate CSF 5-HIAA concentrations below the sample median and filled squares indicate concentrations above the sample median (87 nM). (From Nördstrom P, Samuelsson M, Asberg M, Träskman-Bendz L, Aberg-Wistedt A, Nordin C, Bertilsson L. CSF concentrations 5-HIAA predicts suicide risk after attempted suicide. *Suicide Life Threat Behav.* 1994;24:1, with permission.)

**Genetic Factors.** Suicidal behavior, as with other psychiatric disorders, tends to run in families. In psychiatric patients, a family history of suicide increases the risk of attempted suicide and that of completed suicide in most diagnostic groups. In medicine, the strongest evidence for involvement of genetic factors comes from twin and adoption studies and from molecular genetics. Such studies in suicide are reviewed below.

**Twin Studies.** A landmark study in 1991 investigated 176 twin pairs in which one twin had committed suicide. In nine of these twin pairs, both twins had committed
suicide. Seven of these nine pairs concordant for suicide were found among the 62 monozygotic pairs, whereas two pairs concordant for suicide were found among the 114 dizygotic twin pairs. This twin group difference for concordance for suicide (11.3 vs. 1.8 percent) is statistically significant ($P < .01$).

Another study collected a group of 35 twin pairs in which one twin had committed suicide and the living co-twin was interviewed. Ten of the 26 living monozygotic cotwins had themselves attempted suicide, compared with 0 of the 9 living dizygotic cotwins ($P < .04$). Although monozygotic and dizygotic twins may have some differing developmental experiences, these results show that monozygotic twin pairs have significantly higher concordance for both suicide and attempted suicide, which suggests that genetic factors may play a role in suicidal behavior.

**Danish-American Adoption Studies.** The strongest evidence suggesting the presence of genetic factors in suicide comes from adoption studies carried out in Denmark. A screening of the registers of causes of death revealed that 57 of 5,483 adoptees in Copenhagen eventually committed suicide. They were matched with adopted controls. Searches of the causes of death revealed that 12 of the 269 biological relatives of these 57 adopted suicide victims had themselves committed suicide, compared with only 2 of the 269 biological relatives of the 57 adopted controls. This is a highly significant difference for suicide between the two groups of relatives. None of the adopting relatives of either the suicide or control group had committed suicide.

In a further study of 71 adoptees with mood disorder, adoptee suicide victims with a situational crisis or impulsive suicide attempt or both (particularly) had more biological relatives who had committed suicide than controls had. This led to the suggestion that a genetic factor lowering the threshold for suicidal behavior may lead to an inability to control impulsive behavior. Psychiatric disorders or environmental stress may serve “as potentiating mechanisms which foster or trigger the impulsive behavior, directing it toward a suicidal outcome.”

**Molecular Genetic Studies.** Tryptophan hydroxylase (TPH) is an enzyme involved in the biosynthesis of serotonin. A polymorphism in the human $TPH$ gene has been identified, with two alleles—U and L. Because low concentrations of 5-HIAA in CSF are associated with suicidal behavior, it was hypothesized that such individuals may have alterations in genes controlling serotonin synthesis and metabolism. It was found that impulsive alcoholics, who had low CSF 5-HIAA concentrations, had more LL and UL genotypes. Furthermore, a history of suicide attempts was significantly associated with TPH genotype in all the violent alcoholics; 34 of the 36 violent subjects who attempted suicide had either the UL or LL genotype. Thus, it was concluded that the presence of the L allele was associated with an increased risk of suicide attempts.

Also, a history of multiple suicide attempts was found most often in subjects with the LL genotype and to a lesser extent among those with the UL genotype (Fig. 23.1-3). This led to the suggestion that the L allele was associated with repetitive suicidal behavior. The presence of one TPH*L allele may indicate a reduced capacity to hydroxylate
tryptophan to 5-hydroxytryptophan in the synthesis of serotonin, producing low central serotonin turnover and, thus, a low concentration of 5-HIAA in CSF.

**FIGURE 23.1-3**
Relation between tryptophan hydroxylase (TPH) genotype and lifetime history of multiple suicide attempts. For each genotype, the fraction of subjects having each genotype (UU, squares; UL, circles; LL, triangles) is plotted against the number of suicide attempts they have made in their lives. (From Nielsen D, Goldman D, Virkkunen M, Tokola R, Rawlings R, Linnoila M. Suicidality and 5-hydroxyindoleacetic acid concentration associated with a tryptophan hydroxylase polymorphism. *Arch Gen Psychiatry.* 1994;51:34, with permission.)

**Parasuicidal Behavior.** *Parasuicide* is a term introduced to describe patients who injure themselves by self-mutilation (e.g., cutting the skin), but who usually do not wish to die. Studies show that about 4 percent of all patients in psychiatric hospitals have cut themselves; the female-to-male ratio is almost 3 to 1. The incidence of self-injury in psychiatric patients is estimated to be more than 50 times that in the general population. Psychiatrists note that so-called cutters have cut themselves over several years. Self-injury is found in about 30 percent of all abusers of oral substances and 10 percent of all intravenous users admitted to substance-treatment units.

These patients are usually in their 20s and may be single or married. Most cut delicately, not coarsely, usually in private with a razor blade, knife, broken glass, or mirror. The wrists, arms, thighs, and legs are most commonly cut; the face, breasts, and abdomen are cut infrequently. Most persons who cut themselves claim to experience no pain and give reasons for this behavior such as anger at themselves or others, relief of tension, and the wish to die. Most are classified as having personality disorders and are significantly more introverted, neurotic, and hostile than controls. Alcohol abuse and other substance abuse are common, and most cutters have attempted suicide. Self-mutilation has been viewed as localized self-destruction, with mishandling of aggressive impulses caused by a person’s unconscious wish to punish himself or herself or an
Clinicians must assess an individual patient’s risk for suicide on the basis of a clinical examination. The predictive items associated with suicide risk are listed in Table 23.1-2. Suicide is grouped into high-risk–related and low-risk–related factors (Table 23.1-3). High-risk characteristics include more than 45 years of age, male gender, alcohol dependence (the suicide rate is 50 times higher in alcohol-dependent persons than in those who are not alcohol dependent), violent behavior, previous suicidal behavior, and previous psychiatric hospitalization.

(From Slaby AE. Outpatient management of suicidal patients in the era of managed care. Prim Psychiatry. 1995;Apr:43, with permission.)
It is important that questions about suicidal feelings and behaviors be asked, often directly. Asking depressed patients whether or not they have had thoughts of wanting to kill themselves does not plant the seed of suicide. To the contrary, it may be the first opportunity a patient has had to talk about suicidal ideation that may have been present for some time.

The American Psychiatric Association (APA) developed practice guidelines for treating patients with suicidal behaviors, and Table 23.1-4 lists a host of questions that can help the clinician assess suicide risk.

Table 23.1-4
Questions about Suicidal Feelings and Behaviors
Treatment

Most suicides among psychiatric patients are preventable, because evidence indicates that inadequate assessment or treatment is often associated with suicide. Some patients experience suffering so great and intense, or so chronic and unresponsive to treatment,
that their eventual suicides may be perceived as inevitable. Such patients are relatively uncommon, however (see discussion of inevitable suicide below). Other patients have severe personality disorders, are highly impulsive, and commit suicide spontaneously, often when dysphoric, intoxicated, or both.

The evaluation for suicide potential involves a complete psychiatric history; a thorough examination of the patient’s mental state; and an inquiry about depressive symptoms, suicidal thoughts, intents, plans, and attempts. A lack of future plans, giving away personal property, making a will, and having recently experienced a loss all imply increased risk of suicide. The decision to hospitalize a patient depends on diagnosis, depression severity and suicidal ideation, the patient’s and the family’s coping abilities, the patient’s living situation, availability of social support, and the absence or presence of risk factors for suicide.

**Inpatient versus Outpatient Treatment**

Whether to hospitalize patients with suicidal ideation is the most important clinical decision to be made. Not all such patients require hospitalization; some can be treated on an outpatient basis. But the absence of a strong social support system, a history of impulsive behavior, and a suicidal plan of action are indications for hospitalization. To decide whether outpatient treatment is feasible, clinicians should use a straightforward clinical approach: Ask patients who are considered suicidal to agree to call when they become uncertain about their ability to control their suicidal impulses. Patients who can make such an agreement with a doctor with whom they have a relationship reaffirm the belief that they have sufficient strength to control such impulses and to seek help.

In return for a patient’s commitment, clinicians should be available to the patient 24 hours a day. If a patient who is considered seriously suicidal cannot make the commitment, immediate emergency hospitalization is indicated; both the patient and the patient’s family should be so advised. If, however, the patient is to be treated on an outpatient basis, the therapist should note the patient’s home and work telephone numbers for emergency reference; occasionally, a patient hangs up unexpectedly during a late night call or gives only a name to the answering service. If the patient refuses hospitalization, the family must take the responsibility to be with the patient 24 hours a day.

According to Edwin S. Shneidman, a clinician has several practical preventive measures for dealing with a suicidal person: reducing the psychological pain by modifying the patient’s stressful environment, enlisting the aid of the spouse, the employer, or a friend; building realistic support by recognizing that the patient may have a legitimate complaint; and offering alternatives to suicide.

Many psychiatrists believe that any patient who has attempted suicide, despite its lethality, should be hospitalized. Although most of these patients voluntarily enter a hospital, the danger to self is one of the few clear-cut indications currently acceptable in all states for involuntary hospitalization. In a hospital, patients can receive antidepressant or antipsychotic medications as indicated; individual therapy, group
therapy, and family therapy are available, and patients receive the hospital’s social support and sense of security. Other therapeutic measures depend on patients’ underlying diagnoses. For example, if alcohol dependence is an associated problem, treatment must be directed toward alleviating that condition.

Although patients classified as acutely suicidal may have favorable prognoses, chronically suicidal patients are difficult to treat, and they exhaust the caretakers. Constant observation by special nurses, seclusion, and restraints cannot prevent suicide when a patient is resolute. ECT may be necessary for some severely depressed patients, who may require several treatment courses.

Useful measures for the treatment of depressed suicidal inpatients include searching patients and their belongings on arrival in the ward for objects that could be used for suicide and repeating the search at times of exacerbation of the suicidal ideation. Ideally, suicidally depressed inpatients should be treated on a locked ward where the windows are shatterproof, and the patient’s room should be located near the nursing station to maximize observation by the nursing staff. The treatment team must assess how much to restrict the patient and whether to make regular checks or use continuous direct observation.

Vigorous treatment with antidepressant or antipsychotic medication should be initiated, depending on the underlying disorder. Some medications (e.g., risperidone [Risperdal]) have both antipsychotic and antidepressant effects and are useful when the patient has signs and symptoms of both psychosis and depression.

Supportive psychotherapy by a psychiatrist shows concern and may alleviate some of a patient’s intense suffering. Some patients may be able to accept the idea that they are suffering from a recognized illness and that they will probably make a complete recovery. Patients should be dissuaded from making major life decisions while they are suicidally depressed, because such decisions are often morbidly determined and may be irrevocable. The consequences of such bad decisions can cause further anguish and misery when the patient has recovered.

Patients recovering from a suicidal depression are at particular risk. As the depression lifts, patients become energized and, thus, are able to put their suicidal plans into action (paradoxical suicide). A further complication is the activating effect of serotonergic drugs, such as fluoxetine (Prozac), which are effective antidepressants, especially with suicidally depressed patients. Such agents may improve psychomotor withdrawal, thus permitting the patient to act on preexisting suicidal impulses because they have more energy. Sometimes, depressed patients, with or without treatment, suddenly appear to be at peace with themselves because they have reached a secret decision to commit suicide. Clinicians should be especially suspicious of such a dramatic clinical change, which may portend a suicide attempt. Although rare, some patients lie to the psychiatrist about their suicidal intent, thus subverting the most careful clinical assessment.

A patient may commit suicide even when in the hospital. According to one survey, about 1 percent of all suicides were committed by patients who were being treated in general medical-surgical or psychiatric hospitals, but the annual suicide rate in
psychiatric hospitals is only 0.003 percent.

Table 23.1-5 lists guidelines for selecting a treatment setting for suicidal patients.

Table 23.1-5
Guidelines for Selecting a Treatment Setting for Patients at Risk for Suicide or Suicidal Behaviors

<table>
<thead>
<tr>
<th>Admission generally indicated: high risk of suicide</th>
<th>Need for supervised setting for medication trial or electroconvulsive therapy</th>
</tr>
</thead>
<tbody>
<tr>
<td>After a suicide attempt or aborted suicide attempt if:</td>
<td>Need for skilled observation, clinical tests, or diagnostic assessments that require a structured setting</td>
</tr>
<tr>
<td>Patient is psychotic</td>
<td>Limited family and/or social support, including lack of stable living situation</td>
</tr>
<tr>
<td>Attempt was violent, near-lethal, or premeditated</td>
<td>Lack of an ongoing clinician-patient relationship or lack of access to timely outpatient follow-up</td>
</tr>
<tr>
<td>Precautions were taken to avoid rescue or discovery</td>
<td>In the absence of suicide attempts or reported suicidal ideation/plans/intent but evidence from the psychiatric evaluation and/or history from others suggests a high level of suicide risk and a recent acute increase in risk</td>
</tr>
<tr>
<td>Persistent plan and/or intent is present</td>
<td>Release from emergency department with follow-up recommendations may be possible: lesser risk</td>
</tr>
<tr>
<td>Distress is increased or patient regrets surviving</td>
<td>After a suicide attempt or in the presence of suicidal ideation/plan when: Suicidality is a reaction to precipitating events (e.g., examination failure, relationship difficulties), particularly if the patient’s view of situation has changed since coming to emergency department</td>
</tr>
<tr>
<td>Patient is male, &gt;45 years of age, especially with new onset of psychiatric illness or suicidal thinking</td>
<td>Plan/method and intent have low lethality</td>
</tr>
<tr>
<td>Patient has limited family and/or social support, including lack of stable living situation</td>
<td>Patient has stable and supportive living situation</td>
</tr>
<tr>
<td>Current impulsive behavior, severe agitation, poor judgment, or refusal of help is evident</td>
<td>Patient is able to cooperate with recommendations for follow-up, with greater contact if possible, if patient is currently in treatment</td>
</tr>
<tr>
<td>Patient has change in mental status with a metabolic, toxic, infectious, or other etiology requiring further workup in a structured setting</td>
<td>Outpatient treatment may be more beneficial than hospitalization: lesser risk of suicide</td>
</tr>
</tbody>
</table>

In the presence of suicidal ideation with:
- Specific plan with high lethality
- High suicidal intent

Admission may be necessary: moderate risk of suicide

After a suicide attempt or aborted suicide attempt, except in circumstances for which admission is generally indicated in the presence of suicidal ideation with:
- Psychosis
- Major psychiatric disorder
- Past attempts, particularly if medically serious
- Possibly contributing medical condition (e.g., acute neurological disorder, cancer, infection)
- Lack of response to or inability to cooperate with partial hospital or outpatient treatment

Liability issues stemming from suicides in psychiatric hospitals frequently involve questions about a patient’s rate of deterioration, the presence during hospitalization of clinical signs indicating risk, and psychiatrists’ and staff members’ awareness of, and response to, these clinical signs.

In about half of the cases in which suicides occur while patients are on a psychiatric unit, a lawsuit results. Courts expect suicides to occur; do not require zero suicide rates, but do require periodic patient evaluation for suicidal risk, formulation of a treatment plan with a high level of security, and having staff members follow the treatment plan.

Currently, suicide and attempted suicide are variously viewed as a felony and a misdemeanor, respectively; in some states, the acts are not considered crimes but...
unlawful under common law and statutes. Aiding and abetting a suicide adds another dimension to the legal morass; some court decisions have held that although neither suicide nor attempted suicide is punishable, anyone who assists in the act may be punished.

**National Strategy for Suicide Prevention**

In 2001, Surgeon General David Satcher organized the National Strategy for Suicide Prevention, under the auspices of the National Institutes of Health (NIH). The National Strategy for Suicide Prevention has set specific goals and objectives to reduce suicide (Table 23.1-6).

<table>
<thead>
<tr>
<th>Goals to Reduce Suicide</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Promote awareness that suicide is a public health problem that is preventable</td>
</tr>
<tr>
<td>2. Develop broad-based support for suicide prevention</td>
</tr>
<tr>
<td>3. Develop and implement strategies to reduce the stigma associated with being a consumer of mental health, substance abuse, and suicide prevention services</td>
</tr>
<tr>
<td>4. Develop and implement suicide prevention programs</td>
</tr>
<tr>
<td>5. Promote efforts to reduce access to lethal means and methods of self-harm</td>
</tr>
<tr>
<td>6. Implement training for recognition of at-risk behavior and delivery of effective treatment</td>
</tr>
<tr>
<td>7. Develop and promote effective clinical and professional practices</td>
</tr>
<tr>
<td>8. Improve access to, and community linkages with, mental health and substance abuse services</td>
</tr>
<tr>
<td>9. Improve reporting and portrayals of suicidal behavior, mental illness, and substance abuse in the entertainment and news media</td>
</tr>
<tr>
<td>10. Promote and support research on suicide and suicide prevention</td>
</tr>
<tr>
<td>11. Improve and expand surveillance systems</td>
</tr>
</tbody>
</table>

The National Strategy for Suicide Prevention creates a framework for suicide prevention for the nation. It is designed to encourage and empower groups and individuals to work together. The stronger and broader the support and collaboration on suicide prevention, the greater the chance of success for this public health initiative. Suicide and suicidal behaviors can be reduced as the general public gains more understanding about (1) the extent to which suicide is a problem, (2) the ways in which it can be prevented, and (3) the roles individuals and groups can play in prevention efforts.

**SUICIDES INVOLVING OTHER DEATHS**

**Victim-Precipitated Homicide**

The phenomenon of using others, usually police, to kill oneself is well known to law enforcement personnel. Described by Marvin Wolfgang, the classic situation is exemplified by a person holding up a gas station or all-night store and brandishing a
gun, which he threatens to use on the police when they arrive. They then shoot him, thinking that it is in self-defense. The psychology of such victims is not clear, except that they apparently believe this is the only way they can die.

A 25-year-old white divorced father of twin 3-year-old boys had been threatening to his wife, and, consequently, she had an order of restraint placed on him. Nonetheless, one evening, he went to her home, carrying a realistic-looking toy pistol in his pocket “to give her a scare.” She refused to admit him, and, when he began to create a scene, she called the police. When three police officers arrived, he refused to leave, pointed the toy pistol at them and taunted them to shoot him. They drew their revolvers, ordered him to drop his “weapon” (which he did), and restrained him. They took him to a local emergency department, where the nurse’s admission note read: “divorced and angry man threatened others with a toy pistol.” The on-call psychiatrist saw him briefly; the patient denied suicidal or homicidal intent; and the psychiatrist concluded that it was safe to discharge him (as a “situational problem–marital issues”). The following day, he killed himself by using carbon monoxide. Although this was not a case of “completed” victim-precipitated homicide, hospital staff failed to perceive that this represented “attempted” victim-precipitated homicide and was an act of high risk. Noting that he “threatened others with a toy pistol” trivialized the gravity of pointing what appears to be a genuine gun at armed police and telling them to shoot. In effect, he had given up control over this life-threatening situation to the police, and only their self-restraint protected him from being killed that evening.

**Murder-Suicides**

Murder-suicides receive a disproportionate amount of attention because they are dramatic and tragic. Unless it is a pact between two truly consenting adults, such events testify to the enormous amount of aggression inherent in many suicides—in addition to the depression. Furthermore, what appears to be a pact is often, in fact, more of a coercion (or flat-out murder) than a true pact among equals. Pacts tend to be made more often by females or elderly couples.

**Terrorist Suicides.** Terrorist-bomber suicides represent a special category of murder-suicides, one in which there is no question of willingness of the victim’s part and in which the victims are unknown to the perpetrators except in some generic, group sense (e.g., Jews, Westerners). Some suicide experts do not classify these as “true” suicides because they differ in so many domains from typical suicides (*Table 23.1-7*).
Although many terrorists are recruited from poorer and less-educated classes, it is surprising that a very large proportion of terrorist bombers are instead from middle-class, well-educated, and possibly less-fundamentalist populations. Because suicide means to take one's life, it is hard to exclude these terrorist deaths from such a classification.

**INEVITABLE SUICIDE**

Not all suicides are preventable; some may be inevitable. In fact, over one third of all completed suicides occur in persons who are receiving treatment for a psychiatric disorder, most commonly depression, bipolar disorder, or schizophrenia. It is not unreasonable to assume that some of those patients received the best care available, but that their suicides could not be prevented.

Some clinicians believe that viewing certain suicides as being inevitable may lead to therapeutic nihilism, others feel it may cause both clinicians and patients to lose hope. But inevitable suicide can only be determined a posteriori, after all known facts of a particular suicide have been analyzed and synthesized. And if it cannot be predicted there is no reason for therapeutic nihilism or for treatment efforts to be influenced negatively; indeed viewing some suicides as possibly inevitable may encourage clinicians to increase their therapeutic zeal to prevent or postpone the inevitable from happening.

Certain criteria must be met for a particular suicide to be considered inevitable. Most important is a strong genetic history of suicide in one or more family members as well as heavy genetic loading for mental illness. Although a strong genetic diathesis for suicide is associated with completed suicide, it is not, in and of itself, sufficient. Other risk factors must also be present, numerous, and at the extreme end of profound pathology. Among the many risk factors (as described above) are a history of physical, emotional, or sexual abuse, especially during childhood; divorce; unemployment; male gender; recent discharge from a psychiatric hospital; prior suicide attempts; alcoholism or other substance abuse; a history of panic attacks; and the presence of a medical illness. Persistent suicidal thoughts, especially coupled with a plan, are particularly dangerous. As mentioned above, inevitability presumes that these risk factors are numerous, severe, and present in severe degrees.

Finally, to consider suicide inevitable the patient must have received the highest standard of treatment and that treatment must have failed. Inevitability assumes, among many other factors, that everything that could have been done was done—and done correctly—yet the patient died.
The case of Ernest Hemingway may be an example of inevitable suicide. Including Ernest, five people committed suicide in the Hemingway family. His father, brother, sister, and granddaughter all killed themselves. In addition, one of his sons suffered from major depression and underwent several courses of ECT during his lifetime.

Toward the end of his life, Hemingway had several hospitalizations for depression accompanied by suicide attempts. His last hospitalization was in 1961 at the Mayo Clinic, where he had been admitted in a severely depressed state after yet another suicide attempt. He was delusional (thinking that people were following him with deadly intent), had cognitive difficulties that prevented him from writing creatively, was physically ill with cardiovascular disease, and had been drinking heavily. He was hospitalized for 7 weeks, during which time he was treated with antidepressants, ECT, and psychotherapy. On June 26, 1961, he was discharged from the hospital. As Hemingway was leaving the hospital, in a last conversation, he was purported to have said, “You and I both know what I am going to do to myself one day.”

On July 2, 1961, at 7:30 in the morning, 6 days after discharge, Hemingway put a shotgun to his head and pulled the trigger.

Hemingway had all of the biopsychosocial determinants of an inevitable suicide. There was heavy genetic loading for suicide, severe psychiatric disorder characterized by persecutory delusions, substance abuse, and other risk factors such as profound suicidal ideation and prior suicide attempts. In addition, Hemingway was the victim of severe childhood trauma, which increased his vulnerability to suicide.

As yet, there are insufficient data to predict the inevitability of a particular suicide. The paradigm of inevitability, however, may serve as a stimulus to increase root cause analysis into this phenomenon. The history of medicine is replete with disorders that inexorably led to death but which are now curable and suicide may one day join those ranks.

SURVIVING SUICIDE

To be a suicide survivor refers to those who have lost a loved one to suicide, not to someone who has attempted suicide but lived. The toll on suicide survivors appears greater than that by other deaths, mainly because the opportunities for guilt are so great. Survivors feel that the loved one intentionally and willfully took his or her life and that if only the survivor had done something differently, the decedent would still be here. Because the decedent cannot tell them otherwise, survivors are at the mercy of their often merciless consciences.

What is generally more accurate is that the decedents were not entirely willful but were themselves victims of their own genetic or lifetime experience predispositions to depression and suicide. For children, in particular, the loss of a parent to suicide feels like a shameful abandonment for which the child may blame himself or herself. For parents of children who have killed themselves, their grief is compounded not only by
having lost a part of themselves, but also by having failed in what they perceive as their responsibility for the total feelings of their child. To provide mutual support, survivors of suicide groups have appeared throughout the United States, generally led by nonprofessional survivors themselves. Therapists who have lost patients to suicide comprise another survivor group—one too often ignored and unsupported, despite their own considerable suffering and sense of guilt and compounded by the specter of litigation potentially being brought to bear.

# 23.2 Psychiatric Emergencies in Adults
A psychiatric emergency is any disturbance in thoughts, feelings, or actions for which immediate therapeutic intervention is necessary. For a variety of reasons—such as the growing incidence of violence, the increased appreciation of the role of medical disease in altered mental status, and the epidemic of alcoholism and other substance use disorders—the number of emergency patients is on the rise. The widening scope of emergency psychiatry goes beyond general psychiatric practice to include such specialized problems as the abuse of substances, children, and spouses; violence in the form of suicide, homicide, and rape; and such social issues as homelessness, aging, competence, and acquired immune deficiency syndrome (AIDS). The emergency psychiatrist must be up to date on medicolegal issues and managed care. This section provides an overview of psychiatric emergencies in general and in adults in particular. Section 23.3 covers psychiatric emergencies in children.

**TREATMENT SETTINGS**

Most emergency psychiatric evaluations are done by nonpsychiatrists in a general medical emergency room setting, but specialized psychiatric services are increasingly favored. Regardless of the type of setting, an atmosphere of safety and security must prevail. An adequate number of staff members—including psychiatrists, nurses, aides, and social workers—must be present at all times. Additional personnel to help out in times of overcrowding should be available. Specific responsibilities, such as the use of restraints, should be clearly defined and practiced by the entire emergency team. Clear communication and lines of authority are essential. The organization of the staff into multidisciplinary teams is desirable.

Children and young adolescents are best served in a pediatric setting (see Section 23.3). Unless there is a risk of behavioral problems or of their leaving the hospital against advice, they need not be sent to the adult psychiatric emergency service.

Immediate access to the medical emergency room and to appropriate diagnostic services is necessary because one third of medical conditions present with psychiatric manifestations. The full spectrum of psychopharmacological options should be available to the psychiatrist.

Violence in the emergency service cannot be condoned or tolerated. The code of conduct expected of staff members and patients must be posted and understood from the time of the patient’s arrival in the emergency room. Security is best managed as a clinical issue by the clinical staff, not by law enforcement personnel. Whenever possible, agitated and threatening patients should be sequestered from the nonagitated. Seclusion and restraint rooms should be located close to the nursing station for close observation.

The entire staff must understand that patients in physical and emotional distress are fragile and that various expectations and fantasies, often unrealistic, influence their responses to treatment. For example, a man with impaired reality testing who is brought in by the police against his will may not understand that the clinician is interested in helping him. Other patients, influenced by previous unsatisfactory treatment experiences, may be hostile. A high percentage of patients believe that
psychiatrists can read minds or are only interested in admitting patients to lock them away. Such people see little point in openly discussing their problems. Many people have an inaccurate understanding of their rights as patients. All clinical interventions must take those expectations and attitudes into account to minimize the possibility of misunderstanding and consequent problems.

**EPIDEMIOLOGY**

Psychiatric emergency rooms are used equally by men and women and more by single than by married persons. About 20 percent of these patients are suicidal, and about 10 percent are violent. The most common diagnoses are mood disorders (including depressive disorders and manic episodes), schizophrenia, and alcohol dependence. About 40 percent of all patients seen in psychiatric emergency rooms require hospitalization. Most visits occur during the night hours, but usage difference is not based on the day of the week or the month of the year. Contrary to popular belief, studies have not found that use of psychiatric emergency rooms increases during the full moon or the Christmas season.

**EVALUATION**

The primary goal of an emergency psychiatric evaluation is the timely assessment of the patient in crisis. To that end, the physician must make an initial diagnosis, identify the precipitating factors and immediate needs, and begin treatment or refer the patient to the most appropriate treatment setting. In view of the unpredictable nature of emergency room work, with many patients presenting both physical and emotional complaints, and in view of the limited space and the competition for ancillary services, a pragmatic approach to the patient is required. Sometimes, moving the patient out of the emergency room into the most appropriate diagnostic or treatment setting is best for the patient. Medical emergencies are generally better managed elsewhere in the system. Keeping the number of emergency patients in one place to a minimum reduces the chance of agitation and violence.

The standard psychiatric interview—consisting of a history, a mental status examination, and, when appropriate and depending on the rules of the emergency room, a full physical examination and ancillary tests—is the cornerstone of the emergency room evaluation. The emergency room psychiatrist, however, must be ready to introduce modifications as needed. For example, the emergency psychiatrist may have to structure the interview with a rambling manic patient, medicate or restrain an agitated patient, or forgo the usual rules of confidentiality to assess an adolescent’s risk of suicide. In general, any strategy introduced in the emergency room to accomplish the goal of assessing the patient is considered consistent with good clinical practice as long as the rationale for the strategy is documented in the medical record.

What constitutes a psychiatric emergency is highly subjective. The emergency room has increasingly come to serve as an admitting area, a holding room, a detoxification center, and a private medical office. Such medical conditions as head
Traumas, acute intoxications, withdrawal states, and AIDS encephalopathies may present with acute psychiatric manifestations. The emergency psychiatrists must rapidly assess and distinguish the truly emergency psychiatric patients from those who are less acutely ill and from nonpsychiatric emergencies. A triage system using psychiatrists, nurses, and psychiatric social workers is an efficient and effective way to identify emergency, urgent, and nonurgent patients, who can then be prioritized for care (Fig. 23.2-1).

**FIGURE 23.2-1**
Evaluation and treatment of psychiatric emergencies.

In one model, every patient who comes to the emergency room is assessed by a triage nurse on arrival to ascertain the patient’s chief complaint, clinical condition, and vital signs. The psychiatrist then briefly meets with the patient and other significant people involved in the case—family members, emergency medical service technicians, and police—to assign the patient to one of the three categories—emergency, urgent, and nonurgent—or to refer the patient to an appropriate treatment setting, such as the medical emergency room. Having a senior clinician perform that task ensures rapid identification of the most urgent and troublesome cases, an appropriate allocation of resources, and an answer to the most common question heard in the emergency room: “When am I going to see a doctor?”

The psychiatrist then assigns clinical responsibility for each patient to the appropriate personnel. As the evaluation often stretches over more than one shift, a careful procedure to transfer responsibility and to pass along information from tour to tour must be built into the system by using visual, oral, and written communications. A request for old records should be made automatically for every patient who is assigned to the emergency room. Each emergency should be judged on its own merits, but information from previous records and from workers in the field and family members can be of crucial importance in assessing patients, especially patients who are psychotic, frightened, or otherwise unable or unwilling to cooperate in giving a good history.

A multilingual staff and a hospital language bank that lists bilingual staff members and other translation services should be readily available to the psychiatrist. The use of the patient’s friends or family members as translators is not desirable because of the possibility of unconscious or deliberate denial or distortion of the clinical picture stemming from their involvement with the patient.

An initial assessment of the patient’s total biopsychosocial needs is optimal, but the patient’s emergency status, other patients waiting to be seen, and the constraints of the emergency room setting often make such a full assessment a moot point. At a minimum, the emergency evaluation should address the following five questions before any
disposition is decided on: (1) Is it safe for the patient to be in the emergency room? (2) Is the problem organic, functional, or a combination? (3) Is the patient psychotic? (4) Is the patient suicidal or homicidal? (5) To what degree is the patient capable of self-care? Table 23.2-1 provides a general strategy for evaluating patients.

Table 23.2-1

General Strategy in Evaluating the Patient

<table>
<thead>
<tr>
<th>I. Self-protection</th>
</tr>
</thead>
<tbody>
<tr>
<td>A. Know as much as possible about the patients before meeting them.</td>
</tr>
<tr>
<td>B. Leave physical restraint procedures to those who are trained.</td>
</tr>
<tr>
<td>C. Be alert to risks of impending violence.</td>
</tr>
<tr>
<td>D. Attend to the safety of the physical surroundings (e.g., door access, room objects).</td>
</tr>
<tr>
<td>E. Have others present during the assessment if needed.</td>
</tr>
<tr>
<td>F. Have others in the vicinity.</td>
</tr>
<tr>
<td>G. Attend to developing an alliance with the patient (e.g., do not confront or threaten patients with paranoid psychoses).</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>II. Prevent harm</th>
</tr>
</thead>
<tbody>
<tr>
<td>A. Prevent self-injury and suicide. Use whatever methods are necessary to prevent patients from hurting themselves during the evaluation.</td>
</tr>
<tr>
<td>B. Prevent violence toward others. During the evaluation, briefly assess the patient for the risk of violence. If the risk is deemed significant, consider the following options:</td>
</tr>
<tr>
<td>1. Inform the patient that violence is not acceptable.</td>
</tr>
<tr>
<td>2. Approach the patient in a nontreating manner.</td>
</tr>
<tr>
<td>3. Reassure, calm, or assist the patient's reality testing.</td>
</tr>
<tr>
<td>4. Offer medication.</td>
</tr>
<tr>
<td>5. Inform the patient that restraint or seclusion will be used if necessary.</td>
</tr>
<tr>
<td>6. Have teams ready to restrain the patient.</td>
</tr>
<tr>
<td>7. When patients are restrained, always closely observe them, and frequently check their vital signs. Isolate restrained patients from surrounding agitating stimuli. Immediately plan a further approach—medication, reassurance, medical evaluation.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>III. Rule out organic mental disorders.</th>
</tr>
</thead>
<tbody>
<tr>
<td>IV. Rule out impending psychosis.</td>
</tr>
</tbody>
</table>

Patient Safety

Physicians should consider the question of the patient’s safety before evaluating every patient. The answer must address the issues of the emergency room’s physical layout, staffing patterns and communication, and patient population. Psychiatrists must then take stock of themselves: Are they in the proper frame of mind to conduct an evaluation? Do any issues in the case spark countertransference reactions? The self-assessment should go on throughout the evaluation. The physical and emotional safety of the patient takes priority over all other considerations. If verbal interventions fail or are contraindicated, the use of medication or restraints must be considered and, if necessary, ordered. Careful attention to the possible outbreak of agitation or disruptive behavior beyond acceptable limits is often the best insurance against untoward occurrences.
Medical or Psychiatric?

The most important question for the emergency psychiatrist to address is whether the problem is medical, psychiatric, or both. Medical conditions—such as diabetes mellitus, thyroid disease, acute intoxications, withdrawal states, AIDS, and head traumas—can present with prominent mental status changes that mimic common psychiatric illnesses (Fig. 23.2-2). Such conditions may be life-threatening if not treated promptly. Generally, the treatment of a medical illness is more definitive and the prognosis is better than for a functional psychiatric disorder. The psychiatrist must consider all casual possibilities.

![Bellevue Hospital emergency ward: a drug addict brought in after having taken an overdose. (Courtesy of Leonard Freed for Magnum Photos, Inc.)](image)

<table>
<thead>
<tr>
<th>Table 23.2-2</th>
</tr>
</thead>
</table>

Once patients are labeled psychiatric, their complaints may not be taken seriously by nonmental health professionals, however, and such patients’ conditions may deteriorate, especially if they have a major Axis I syndrome. Because of such factors as deinstitutionalization, homelessness, and chronic alcoholism, the mentally ill are at great risk of tuberculosis, vitamin deficiencies, and other easily overlooked, but easily treated, conditions. Symptoms such as paranoia, internal preoccupation, and acute psychosis can make a routine medical diagnosis exceedingly difficult. Each patient must be assessed for the possibility that an organic illness is combined with an underlying psychiatric illness. A young man who comes to the emergency room intoxicated or in alcohol withdrawal two or three times a month may one day come with a subdural hematoma as a result of a fall. Table 23.2-2 lists features that point to a medical cause
of a mental disorder.

Table 23.2-2
Features that Point to a Medical Cause of a Mental Disorder

<table>
<thead>
<tr>
<th>Acute onset (within hours or minutes, with prevailing symptoms)</th>

</tr>
</tbody>
</table>

**SPECIFIC INTERVIEW SITUATIONS**

**Psychosis**

Whether the patient is psychotic refers not so much to the diagnosis as to the severity of the patient’s symptoms and the degree of life disruption. The patient’s degree of withdrawal from objective reality, level of affectivity, intellectual functioning, and degree of regression are other important parameters. Impairment in any of those areas may lead to difficulties in conducting an evaluation. Agitated, assaultive behavior or failure to comply with treatment recommendations may also result. A paranoid, hypervigilant patient may misperceive a staff member’s offer of help as an attack and may lash out in self-defense. Command auditory hallucinations may cause a patient to deny symptoms and to throw prescriptions in the garbage immediately after leaving the emergency room. The psychiatrist should be alert to the complications that can arise with patients whose reality testing is impaired and the psychiatrist should modify the approach accordingly.

All communication with patients must be straightforward. All clinical interventions should be briefly explained in language the patient can understand. Psychiatrists should not assume that the patient trusts or believes them or even wants their help. Clinicians must be prepared to structure or to terminate an interview to limit the potential for agitation and regression.

**Depression and Potentially Suicidal Patients**

The clinician should always ask about suicidal ideas as part of every mental status examination, especially if the patient is depressed. The patient may not realize that such symptoms as waking during the night and increased somatic complaints are related to depressive disorders. The patient should be asked directly, “Are you or have you ever been suicidal?” “Do you want to die?” “Do you feel so bad that you might hurt yourself?” Eight of ten persons who eventually kill themselves give warnings of their intent. If the patient admits to a plan of action, that is a particularly dangerous sign. If a patient who has
been threatening suicide becomes quiet and less agitated than before, that may be an ominous sign. The clinician should be especially concerned with the factors listed in Table 23.2-3.

Table 23.2-3
History, Signs, and Symptoms of Suicidal Risk

1. Previous attempt or fantasized suicide
2. Anxiety, depression, exhaustion
3. Availability of means of suicide
4. Concern for effect of suicide on family members
5. Verbalized suicidal ideation
6. Preparation of a will, resignation after agitated depression
7. Proximal life crisis, such as mourning or impending surgery
8. Family history of suicide
9. Pervasive pessimism or hopelessness

A suicide note, a family history of suicide, or previous suicidal behavior on the part of the patient increases the risk of suicide. Evidence of impulsivity or of pervasive pessimism about the future also places the patient at risk. If the physician decides that the patient is in imminent risk for suicidal behavior, the patient must be hospitalized or otherwise protected. A difficult situation arises when the risk does not seem to be immediate but the potential for suicide is present as long as the patient remains depressed. If the psychiatrist decides not to hospitalize the patient immediately, the doctor should insist that the patient promise to call whenever the suicidal pressure mounts.

Violent Patients

Patients may be violent for many reasons, and the interview with a violent patient must attempt to ascertain the underlying cause of the violent behavior, because cause determines intervention. The differential diagnosis of violent behavior includes psychoactive substance-induced organic mental disorder, antisocial personality disorder, catatonic schizophrenia, medical infections, cerebral neoplasms, decompensating obsessive-compulsive personality disorder, dissociative disorders, impulse control disorders, sexual disorders, alcohol idiosyncratic intoxication, delusional disorder, paranoid personality disorder, schizophrenia, temporal lobe epilepsy, bipolar disorder, and uncontrollable violence secondary to interpersonal stress. The psychiatric interview must include questions that attempt to sort out the differential for violent behavior and questions directed toward the prediction of violence.

The best predictors of violent behavior are (1) excessive alcohol intake; (2) a history of violent acts, with arrests or criminal activity; and (3) a history of childhood abuse. Table 23.2-4 lists some of the most significant factors in assessing and predicting violence.

Table 23.2-4
Assessing and Predicting Violent Behavior
Rape is the forceful coercion of an unwilling victim to engage in a sexual act, usually sexual intercourse, although anal intercourse and fellatio can also be acts of rape. As with other acts of violence, rape is a psychiatric emergency that requires immediate, appropriate intervention. Rape victims may suffer sequelae that persist for a lifetime. Rape is a life-threatening experience in which the victim has almost always been threatened with physical harm, often with a weapon. In addition to rape, other forms of sexual abuse include genital manipulation with foreign objects, infliction of pain, and forced sexual activity.

Most rapists are male, and most victims are female. Male rape does occur, however, often in institutions where men are detained (e.g., prisons). Women between the ages of 16 and 24 years are in the highest risk category, but female victims as young as 15 months and as old as 82 years have been raped. More than a third of all rapes are committed by rapists known to the victim, 7 percent by close relatives. A fifth of all rapes involve more than one rapist (gang rape).

Typical reactions in both rape and sexual abuse victims include shame, humiliation, anxiety, confusion, and outrage. Many victims wonder whether they are partly responsible and somehow invited the assault. In fact, victim behavior is less important in precipitating a rape than it is in precipitating a homicide or a robbery. Rape and sexual abuse victims are often confused after the assault. Clinicians should be reassuring, supportive, and nonjudgmental. Inform the patient about the availability of medical and legal services and about rape crisis centers that provide multidisciplinary services.

If possible, a female clinician should evaluate the patient, because the victim may find it easier to talk with a woman than with a man. The evaluation should take place in private. When rape or sexual abuse has not been acknowledged openly, it is usually because many victims hesitate to discuss the assault and thus avoid the topic. If the patient appears to be anxious when questioned about sexual history and avoids the discussion, it is important to validate the patient's avoidance. Recognize that the rape victim has undergone an unanticipated, life-threatening stress. It is legally and therapeutically important to take a detailed and complete history of the attack.

With the patient's written consent, collect evidence, such as semen and pubic hair, that may be used to identify the rapist. Take photographs of the evidence, if possible. The medical record may be used as evidence in criminal proceedings; therefore, meticulous objective documentation of all aspects of the evaluation is essential.
TREATMENT OF EMERGENCIES

Psychotherapy

In an emergency psychiatric intervention, all attempts are made to help patients’ self-esteem. Empathy is critical to healing in a psychiatric emergency. The acquired knowledge of how biogenetic, situational, developmental, and existential forces converge at one point in history to create a psychiatric emergency is tantamount to the maturation of skill in emergency psychiatry. Adjustment disorder in all age groups may result in tantrum-like outbursts of rage. These outbursts are particularly common in marital quarrels, and police are often summoned by neighbors distressed by the sounds of a violent altercation. Such family quarrels should be approached with caution, because they may be complicated by alcohol use and the presence of dangerous weapons. The warring couple frequently turns their combined fury on an unwary outsider. Wounded self-esteem is a major issue, and clinicians must avoid patronizing or contemptuous attitudes and try to communicate an attitude of respect and an authentic peacemaking concern.

In family violence, psychiatrists should note the special vulnerability of selected close relatives. A wife or husband may have a curious masochistic attachment to the spouse and can provoke violence by taunting and otherwise undermining a partner’s self-esteem. Such relationships often end in the murder of the provoking partner and sometimes in the suicide of the other partner—the dynamics behind most so-called suicide pacts. As with many suicidal patients, many violent patients require hospitalization and usually accept the offer of inpatient care with a sense of relief.

More than one psychotherapist or type of psychotherapy is frequently used in emergency therapy. For example, a 28-year-old man, depressed and suicidal after a colostomy for intractable colitis, whose wife was threatening to leave him because of his irritability and their constant altercations, may be referred to a psychiatrist for supportive psychotherapy and antidepressant medication, to a marital therapist with his wife to improve their marital functioning, and to a colostomy support group to learn ways of coping with a colostomy. Emergency psychiatric clinicians are pragmatic; they use every necessary mode of therapeutic intervention available to resolve the crisis and facilitate value exploration and growth, with less concern than usual about diluting a therapeutic relationship. Emergency therapy emphasizes how various psychiatric modalities act synergistically to enhance recovery.

No single approach is appropriate for all persons in similar situations. What does a doctor say to a patient and a family experiencing a psychiatric emergency, such as a suicide attempt or a schizophrenic break? For some, a genetic rationale helps; the information that an illness has a strong biological component relieves some persons. For others, however, this approach underlines a lack of control and increases depression and anxiety. All feel helpless because neither the family nor the patient can alter the behavior to minimize the likelihood of recurrence. Some persons may benefit from an explanation of family or individual dynamics. Others only want someone to listen to
them; in time, they reach their own understanding.

In an emergency situation as in any other psychiatric situation, when a clinician does not know what to say, the best approach is to listen. Persons in crisis reveal how much they need support, denial, ventilation, and words to conceptualize the meaning of their crisis and to discover paths to resolution.

Pharmacotherapy

The major indications for the use of psychotropic medication in an emergency room include violent or assaultive behavior, massive anxiety or panic, and extrapyramidal reactions, such as dystonia and akathisia as adverse effects of psychiatric drugs. Laryngospasm is a rare form of dystonia, and psychiatrists should be prepared to maintain an open airway with intubation if necessary.

Persons who are paranoid or in a state of catatonic excitement require tranquilization. Episodic outbursts of violence respond to haloperidol (Haldol), β-adrenergic receptor antagonists (β-blockers), carbamazepine (Tegretol), and lithium (Eskalith). If a history suggests a seizure disorder, use clinical studies to confirm the diagnosis and an evaluation to ascertain the cause. If the findings are positive, anticonvulsant therapy is initiated or appropriate surgery is provided (e.g., in the case of a cerebral mass). Conservative measures may suffice for intoxication from drugs of abuse. Sometimes, drugs such as haloperidol (5 to 10 mg every half-hour to an hour) are needed until a patient is stabilized. Benzodiazepines may be used instead of, or in addition to, antipsychotics (to reduce the antipsychotic dosage). When a recreational drug has strong anticholinergic properties, benzodiazepines are more appropriate than antipsychotics. Persons with allergic or aberrant responses to antipsychotics and benzodiazepines are treated with amobarbital (Amytal; 130 mg orally or intramuscularly [IM]), paraldehyde, or diphenhydramine (Benadryl; 50 to 100 mg orally or IM).

Violent, struggling patients are subdued most effectively with an appropriate sedative or antipsychotic. Diazepam (Valium; 5 to 10 mg) or lorazepam (Ativan; 2 to 4 mg) may be given slowly intravenously (IV) over 2 minutes. Clinicians must give IV medication with great care to avoid respiratory arrest. Patients who require IM medication can be sedated with haloperidol (5 to 10 mg IM). If the furor is caused by alcohol or is part of a postseizure psychomotor disturbance, the sleep produced by a relatively small amount of an IV medication may go on for hours. On awakening, patients are often entirely alert and rational and typically have complete amnesia about the violent episode.

If the disturbance is part of an ongoing psychotic process and returns as soon as the IV medication wears off, continuous medication may be given. It is sometimes better to use small IM or oral doses at half-hour to 1-hour intervals (e.g., haloperidol, 2 to 5 mg, or diazepam, 20 mg) until the patient is controlled than to use large dosages initially, which can result in an overmedicated patient. As the disturbed behavior is brought under control, successively smaller and less frequent doses should be used. During the preliminary treatment, a patient’s blood pressure and other vital signs should be
Restraints

Restraints are used when patients are so dangerous to themselves or others that they pose a severe threat that cannot be controlled in any other way. Patients may be restrained temporarily to receive medication or for long periods if medication cannot be used. Usually, patients in restraints quiet down after a time. On a psychodynamic level, such patients may even welcome the control of their impulses provided by restraints. Table 23.2-5 provides a summary of the use of restraints.

Table 23.2-5
Use of Restraints

Preferably five or a minimum of four persons should be used to restrain the patient. Leather restraints are the safest and surest type of restraint.

Explain to the patient why he or she is going into restraints.

A staff member should always be visible and reassuring the patient who is being restrained. Reassurance helps alleviate the patient's fear of helplessness, impotence, and loss of control.

Patients should be restrained with legs spread-eagled and one arm restrained to one side and the other arm restrained over the patient's head.

Restraints should be placed so that intravenous fluids can be given, if necessary.

The patient's head is raised slightly to decrease the patient's feelings of vulnerability and to reduce the possibility of aspiration.

The restraints should be checked periodically for safety and comfort.

After the patient is in restraints, the clinician begins treatment, using verbal intervention.

Even in restraints, most patients still take antipsychotic medication in concentrated form.

After the patient is under control, one restraint at a time should be removed at 5-minute intervals until the patient has only two restraints on. Both of the remaining restraints should be removed at the same time, because it is inadvisable to keep a patient in only one restraint.

Always thoroughly document the reason for the restraints, the course of treatment, and the patient's response to treatment while in restraints.

Disposition

In some cases, the usual option of admitting or discharging the patient is not considered optimal. Suspected toxic psychoses, brief decompensations in a patient with a personality disorder, and adjustment reactions to traumatic events, for example, may be best managed in an extended-observation setting. Allowing the patient additional time in a secure environment can result in sufficient improvement or clarification of the issues to make traditional inpatient treatment unnecessary. It can also spare the patient the trauma and stigma of a psychiatric admission and can free up bed space for needier
patients. Crisis intervention for victims of rape and other traumas can also be done in an extended-observation setting.

When the decision is to admit the patient to the hospital, it is preferable to do so on a voluntary basis. Allowing patients that option gives them a sense of control over their lives and of participation in the treatment decisions. Patients who clearly meet involuntary admission criteria on the basis of dangerousness to themselves or to others cannot leave the hospital without further review and can always be converted to involuntary status if warranted.

Because the initial evaluation is often inconclusive, definitive treatment is best deferred until the patient can be further assessed in the inpatient unit or in the outpatient department. When the diagnosis is clear, however, and the patient’s response to previous treatment is known, nothing is gained by delay. For example, a patient with chronic schizophrenia that has decompensated after discontinuing the usual regimen of antipsychotic medication is best served by prompt resumption of treatment.

Even if patients feel comfortable coming to the emergency room in times of need, the emergency psychiatrist should always direct or redirect them to the most appropriate treatment setting. Patients in the psychopharmacology clinic who have missed their regular appointments should be given only enough medication to sustain them until they can be seen in the clinic. Feedback to others treating them should be a matter of course.

The emergency room is often the gateway to the department of psychiatry or the general hospital. First impressions carry a great deal of weight. The kind of attention and concern shown to patients on arrival in the emergency room strongly affects how they will respond to staff members and treatment recommendations and even their treatment compliance long after they have left the emergency room.

**Documentation**

In the interests of good care, respect for patients’ rights, cost control, and medicolegal concerns, documentation has become a central focus for the emergency physician. The medical record should convey a concise picture of the patient, highlighting all pertinent positive and negative findings. Gaps in information and their reason should be mentioned. The names and the telephone numbers of interested parties should be noted. A provisional diagnosis or differential diagnosis must be made. An initial treatment plan or recommendations should clearly follow from the findings of the patient’s history, mental status examination and other diagnostic tests, and the medical evaluation. The writing must be legible. The emergency physician has unusual latitude under the law to perform an adequate initial assessment; however, all interventions and decisions must be thought out, discussed, and documented in the patient’s record.

**Specific Psychiatric Emergencies**

Table 23.2-6 outlines common psychiatric emergencies in alphabetical order. Readers are referred to the index and to specific chapters of this textbook for a thorough

<td>Confusion, agitation, impulsivity</td>
<td>With time and protective environment, symptoms abate</td>
</tr>
<tr>
<td>Alcohol persisting amnestic disorder</td>
<td>Confusion, loss of memory even for all personal identification data</td>
<td>Hospitalization; hypnosis; amobarbital (Amytal) interview; rule out organic cause</td>
</tr>
<tr>
<td>Alcohol persisting dementia</td>
<td>Confusion, agitation, impulsivity</td>
<td>Rule out other causes for dementia; no effective treatment; hospitalization if necessary</td>
</tr>
<tr>
<td>Alcohol psychotic disorder with hallucinations</td>
<td>Vivid auditory (at times visual) hallucinations with affect appropriate to content (often fearful); clear sensorium</td>
<td>Haloperidol for psychotic symptoms</td>
</tr>
</tbody>
</table>
| Alcohol seizures                              | Grand mal seizures; rarely status epilepticus | Diazepam (Valium), phenytoin (Dilantin); prevent by using chlordiazepoxide (Librium) during detoxification
Alcohol withdrawal
- Irritability, nausea, vomiting, insomnia, malaise, autonomic hyperactivity, shakiness

Idiosyncratic alcohol intoxication
- Marked aggressive or assaultive behavior

Korsakoff's syndrome
- Alcohol stigma, amnesia, confabulation

Wernicke's encephalopathy
- Oculomotor disturbances, cerebellar ataxia; mental confusion

Amphetamine (or related substance) intoxication
- Delusions, paranoia; violence; depression (from withdrawal); anxiety, delirium

Anorexia nervosa
- Loss of 25% of body weight of the norm for age and sex

Anticholinergic intoxication
- Psychotic symptoms, dry skin and mouth, hyperpyrexia, mydriasis, tachycardia, restlessness, visual hallucinations

Anticonvulsant intoxication
- Psychosis; delirium

Benzodiazepine intoxication
- Sedation, somnolence, and ataxia

Bereavement
- Guilt feelings, irritability; insomnia; somatic complaints

Borderline personality disorder
- Suicidal ideation and gestures; homicidal ideations and gestures; substance abuse; microsympathetic episodes; burns, cut marks on body

Brief psychotic disorder
- Emotional turmoil, extreme lability; acutely impaired reality testing after obvious psychosocial stress

Bromide intoxication
- Delirium; mania; depression; psychosis

Caffeine intoxication
- Severe anxiety, resembling panic disorder; mania; delirium; agitated depression; sleep disturbance

Cannabis intoxication
- Delusions; panic; dysphoria; cognitive impairment

Catatonic schizophrenia
- Marked psychomotor disturbance (either excitement or stupor); exhaustion; can be fatal

Cimetidine psychotic disorder
- Delirium; delusions

Clonidine withdrawal
- Irritability; psychosis; violence; seizures

Cocaine intoxication and withdrawal
- Paranoia and violence; severe anxiety; manic state; delirium: schizophreniform psychosis; tachycardia, hypertension, myocardial infarction, cerebrovascular disease; depression and suicidal ideation

Delirium
- Fluctuating sensorium; suicidal and homicidal risk; cognitive clouding; visual, tactile, and auditory hallucinations; paranoia

Fluid and electrolytes maintained; sedation with benzodiazepines; restraints; monitoring of vital signs; 100 mg thiamine IM

Generally no treatment required other than protective environment

No effective treatment; institutionalization often needed

Thiamine, 100 mg IV or IM, with MgSO4 given before glucose loading

Antipsychotics; restraints; hospitalization if necessary; no need for gradual withdrawal; antidepressants may be necessary

Hospitalization; electrocardiogram (ECG), fluid and electrolytes; neuroendocrine evaluation

Discontinue drug, IV physostigmine (Antilirium), 0.5 to 2 mg, for severe agitation or fever, benzodiazepines; antipsychotics contraindicated

Dosage of anticonvulsant is reduced

Supportive measures; flumazenil (Romazicon), 7.5 to 45 mg a day, titrated as needed, should be used only by skilled personnel with resuscitative equipment available

Must be differentiated from major depressive disorder; antidepressants not indicated; benzodiazepines for sleep; encouragement of ventilation

Suicidal and homicidal evaluation (if great, hospitalization); small dosages of antipsychotics; clear follow-up plan

Hospitalization often necessary; low dosage of antipsychotics may be necessary but often resolves spontaneously

Serum levels obtained (>50 mg a day); bromide intake discontinued; large quantities of sodium chloride IV or orally; if agitation, paraldehyde or antipsychotic is used

Cessation of caffeine-containing substances; benzodiazepines

Benzodiazepines and antipsychotics as needed; evaluation of suicidal or homicidal risk; symptoms usually abate with time and reassurance

Rapid tranquillization with antipsychotics: monitor vital signs; amobarbital may release patient from catatonic mutism or stupor but can precipitate violent behavior

Reduce dosage or discontinue drug

Symptoms abate with time, but antipsychotics may be necessary; gradual lowering of dosage

Antipsychotics and benzodiazepines; antidepressants or electroconvulsive therapy (ECT) for withdrawal depression if persistent; hospitalization

Evaluate all potential contributing factors and treat each accordingly; reassurance, structure, clues to orientation; benzodiazepines and low-dose, high-potency antipsychotics must be used with extreme care because of their potential to act paradoxically and increase agitation
<table>

<tr>
<th>Disorder</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Delusional disorder</td>
<td>Most often brought into emergency room involuntarily; threats directed toward others</td>
</tr>
<tr>
<td>Dementia</td>
<td>Unable to care for self; violent outbursts; psychosis; depression and suicidal ideation; confusion</td>
</tr>
<tr>
<td>Depressive disorders</td>
<td>Suicidal ideation and attempts; self-neglect; substance abuse</td>
</tr>
<tr>
<td>5-Dopa intoxication</td>
<td>Mania; depression; schizophreniform disorder, may induce rapid cycling in patients with bipolar I disorder</td>
</tr>
<tr>
<td>Dystonia, acute</td>
<td>Intense involuntary spasm of muscles of neck, tongue, face, jaw, eyes, or trunk</td>
</tr>
<tr>
<td>Group hysteria</td>
<td>Groups of people exhibit extremes of grief or other disruptive behavior</td>
</tr>
<tr>
<td>Hallucinogen-induced psychotic disorder with hallucinations</td>
<td>Symptom picture is result of interaction of type of substance, dose taken, duration of action, user's premorbid personality, setting; panic; agitation; atropine psychosis</td>
</tr>
<tr>
<td>Homicidal and assaultive behavior</td>
<td>Marked agitation with verbal threats</td>
</tr>
<tr>
<td>Homosexual panic</td>
<td>Not seen with men or women who are comfortable with their sexual orientation; occurs in those who adamantly deny having any homoerotic impulses; impulses are aroused by talk, a physical overture, or play among same-sex friends, such as wrestling, sleeping together, or touching each other in a shower or hot tub; panicked person sees others as sexually interested in him or her and defends against them</td>
</tr>
<tr>
<td>Hypertensive crisis</td>
<td>Life-threatening hypertensive reaction secondary to ingestion of tyramine-containing foods in combination with monoamine oxidase inhibitors (MAOls); headache, stiff neck, sweating, nausea, vomiting</td>
</tr>
<tr>
<td>Hyperthermia</td>
<td>Extreme excitement or catatonic stupor or both; extremely elevated temperature; violent hyperagitation</td>
</tr>
<tr>
<td>Hyperventilation</td>
<td>Anxiety, terror, clouded consciousness; giddiness, faintness; blurring vision</td>
</tr>
<tr>
<td>Hypothermia</td>
<td>Confusion; lethargy; combativeness; low body temperature and shivering; paradoxical feeling of warmth</td>
</tr>
<tr>
<td>Incest and sexual abuse of child</td>
<td>Suicidal behavior; adolescent crises; substance abuse</td>
</tr>
<tr>
<td>Insomnia</td>
<td>Depression and irritability; early morning agitation; frightening dreams; fatigue</td>
</tr>
<tr>
<td>Intermittent explosive disorder</td>
<td>Brief outbursts of violence; periodic episodes of suicide attempts</td>
</tr>
<tr>
<td>Jaundice</td>
<td>Uncommon complication of low-potency phenothiazine use (e.g., chlorpromazine)</td>
</tr>
<tr>
<td>Leukopenia and agranulocytosis</td>
<td>Side effects within the first 2 months of treatment with antipsychotics</td>
</tr>
<tr>
<td>Lithium (Eskalith) toxicity</td>
<td>Vomiting; abdominal pain; profuse diarrhea; severe tremor, ataxia; coma; seizures; confusion; dysarthria; focal neurological signs</td>
</tr>
<tr>
<td>Antipsychotics if patient will comply (IM if necessary); intensive family intervention; hospitalization if necessary</td>
<td></td>
</tr>
<tr>
<td>Small dosages of high-potency antipsychotics; clues to orientation; organic evaluation, including medication use; family intervention</td>
<td></td>
</tr>
<tr>
<td>Assessment of danger to self; hospitalization if necessary, nonpsychiatric causes of depression must be evaluated</td>
<td></td>
</tr>
<tr>
<td>Lower dosage or discontinue drug</td>
<td></td>
</tr>
<tr>
<td>Decrease dosage of antipsychotic; benztropine or diphenhydramine IM</td>
<td></td>
</tr>
<tr>
<td>Group is dispersed with help of other health care workers; ventilation, crisis-oriented therapy; if necessary, small dosages of benzodiazepines</td>
<td></td>
</tr>
<tr>
<td>Serum and urine screens; rule out underlying medical or mental disorder; benzodiazepines (2 to 20 mg) orally; reassurance and orientation; rapid tranquilization; often responds spontaneously</td>
<td></td>
</tr>
<tr>
<td>Seclusion, restraints, medication</td>
<td></td>
</tr>
<tr>
<td>Ventilation, environmental structuring, and, in some instances, medication for acute panic (e.g., alprazolam, 0.25 to 2 mg) or antipsychotics may be required; opposite-sex clinician should evaluate the patient whenever possible, and the patient should not be touched save for the routine examination; patients have attacked physicians who were examining an abdomen or performing a rectal examination (e.g., on a man who harbors thinly veiled unintegrated homosexual impulses)</td>
<td></td>
</tr>
<tr>
<td>α-Adrenergic blockers (e.g., phenolamine [Rogitine]); nifedipine (Procardia) 10 mg orally; chlorpromazine (Thorazine); make sure symptoms are not secondary to hypotension (side effect of MAOls alone)</td>
<td></td>
</tr>
<tr>
<td>Hydrate and cool; may be drug reaction, so discontinue any drug; rule out infection</td>
<td></td>
</tr>
<tr>
<td>Shift alkalois by having patient breathe into paper bag; patient education; antianxiety agents</td>
<td></td>
</tr>
<tr>
<td>IV fluids and rewarming, cardiac status must be carefully monitored; avoidance of alcohol</td>
<td></td>
</tr>
<tr>
<td>Corroboration of charge, protection of victim; contact social services; medical and psychiatric evaluation; crisis intervention</td>
<td></td>
</tr>
<tr>
<td>Hypnotics only in short term (e.g., triazolam [Halcion], 0.25 to 0.5 mg at bedtime); treat any underlying mental disorder; rules of sleep hygiene</td>
<td></td>
</tr>
<tr>
<td>Benzodiazepines or antipsychotics for short term; long-term evaluation with computed tomography (CT) scan, sleep-deprived electroencephalogram (EEG), glucose tolerance curve</td>
<td></td>
</tr>
<tr>
<td>Change drug to low dosage of a low-potency agent in a different class</td>
<td></td>
</tr>
<tr>
<td>Patient should call immediately for sore throat, fever, etc., and obtain immediate blood count; discontinue drug; hospitalize if necessary</td>
<td></td>
</tr>
<tr>
<td>Lavage with wide-bore tube; osmotic diuresis; medical consultation; may require intensive care unit treatment</td>
<td></td>
</tr>
</tbody>
</table>
Major depressive episode with psychotic features
Major depressive episode symptoms with delusions; agitation, severe guilt; ideas of reference; suicide and homicide risk

Manic episode
Violent, impulsive behavior; indiscriminate sexual or spending behavior; psychosis; substance abuse

Marital crises
Precipitant may be discovery of an extramarital affair, onset of serious illness, announcement of intent to divorce, or problems with children or work; one or both members of the couple may be in therapy or may be psychiatrically ill; one spouse may be seeking hospitalization for the other

Migraine
Throbbing, unilateral headache

Mitrval valve prolapse
Associated with panic disorder; dyspnea and palpitations; fear and anxiety

Neuroleptic malignant syndrome
Hyperthermia; muscle rigidity; autonomic instability; parkinsonian symptoms; catatonic stupor; neurological signs; 10% to 30% mortality; elevated creatine phosphokinase (CPK)

Nitrous oxide toxicity
Euphoria and light-headedness

Nutmeg intoxication
Agitation; hallucinations; severe headaches; numbness in extremities

Opioid intoxication and withdrawal
Intoxication can lead to coma and death; withdrawal is not life-threatening

Panic disorder
Panic, terror; acute onset

Paranoid schizophrenia
Command hallucinations; threat to others or themselves

Parkinsonism
Stiffness, tremor, bradykinesia, flattened affect, shuffling gait, salivation, secondary to antipsychotic medication

Perioral (rabbit) tremor
Perioral tumor (rabbit-like facial grimacing) usually appearing after long-term therapy with antipsychotics

Phencyclidine (or phencyclidine-like intoxication)
Paranoid psychosis; can lead to death; acute danger to self and others

Phencyclidine-induced psychotic disorder
Psychosis and mania in predisposed people

Phenytoin toxicity
Psychosis; paranoia; insomnia; restlessness; nervousness; headache

Phobias
Panic, anxiety; fear

Photosensitivity
Easy sunburning secondary to use of antipsychotic medication

Pigmentary retinopathy
Reported with dosages of thioridazine (Mellaril) of 800 mg a day or above

Antipsychotics plus antidepressants; evaluation of suicide and homicide risk; hospitalization and ECT if necessary

Hospitalization; restraints if necessary; rapid tranquilization with antipsychotics; restoration of lithium levels

Each should be questioned alone regarding extramarital affairs, consultations with lawyers regarding divorce, and willingness to work in crisis-oriented or long-term therapy to resolve the problem; sexual, financial, and psychiatric treatment histories from both, psychiatric evaluation at the time of presentation; may be precipitated by onset of untreated mood disorder or affective symptoms caused by medical illness or insidious-onset dementia; referral for management of the illness reduces immediate stress and enhances the healthier spouse's coping capacity; children may give insights available only to someone intimately involved in the social system

Sumatriptan (Imitrex) 6 mg IM

Echocardiogram; alprazolam or propranolol

Discontinue antipsychotic; IV dantrolene (Dantrium); bromocriptine (Parodel) orally; hydration and cooling; monitor CPK levels

Symptoms abate without treatment within hours of use

Symptoms abate within hours of use without treatment

IV naloxone, narcotic antagonist; urine and serum screens; psychiatric and medical illnesses (e.g., AIDS) may complicate picture

Must differentiate from other anxiety-producing disorders, both medical and psychiatric; ECG to rule out mitral valve prolapse; propranolol (10 to 30 mg); alprazolam (0.25 to 2.0 mg); long-term management may include an antidepressant

Rapid tranquilization; hospitalization; long-acting depot medication; threatened persons must be notified and protected

Oral antiparkinsonian drug for 4 weeks to 3 months; decrease dosage of the antipsychotic

Decrease dosage or change to a medication in another class

Serum and urine assay; benzodiazepines may interfere with excretion; antipsychotics may worsen symptoms because of anticholinergic side effects; medical monitoring and hospitalization for severe intoxication

Reduce dosage or discontinue drug

Symptoms abate with dosage reduction or discontinuation (found in over-the-counter diet aids and oral and nasal decongestants)

Treatment same as for panic disorder

Patient should avoid strong sunlight and use high-level sunscreens

Remain below 800 mg a day of thioridazine

**REFERENCES**

23.3 Psychiatric Emergencies in Children

Few children or adolescents seek psychiatric intervention on their own, even during crisis; thus, most of their emergency evaluations are initiated by parents, relatives, teachers, therapists, physicians, and child protective service workers. Some referrals are for the evaluation of life-threatening situations for the child or for others, such as suicidal behavior, physical abuse, and violent or homicidal behavior. Other urgent but non–life-threatening referrals pertain to children and adolescents with exacerbations of clear-cut serious psychiatric disorders, such as mania, depression, florid psychosis, and school referral. Less diagnostically obvious situations occur when children and adolescents present with a history of a wide range of disruptive, aberrant behaviors, and are accompanied by an overwhelmed, anxious, and distraught adult who perceives the child's actions as an emergency, despite the absence of life-threatening behavior of an obvious psychiatric disorder. In those cases, the spectrum of contributing factors is not immediately clear, and the emergency psychiatrist must assess the entire family or system involved with the child. Familial stressors and parental discord can contribute to the evolution of a crisis for a child. For example, immediate evaluations are sometimes legitimately indicated for a child caught in the crossfire of feuding parents or in a seemingly irreconcilable conflict between a set of parents and a school, therapist, or protective service worker regarding the needs of the child (Table 23.3-1).

An emergency setting is often the site of an initial evaluation of a chronic problem behavior. For example, an identified problem—such as severe tantrums, violence, and destructive behavior in a child—may have been present for months or even years. Yet the initial contact with the mental health system in the emergency room or private
office may be the first opportunity for the child or adolescent to disclose underlying stressors, such as physical or sexual abuse.

In view of the integral relation of severe family dysfunction to childhood behavioral disturbance, the emergency psychiatrist must assess familial discord and psychiatric disorder in family members during an urgent evaluation. One way to make the assessment is to interview the child and the individual family members, both alone and together, and to obtain a history from informants outside the family whenever possible. Noncustodial parents, therapists, and teachers may add valuable information regarding the child’s daily functioning. Many families, especially those with mental illness and severe dysfunction, may have little or no inclination to seek psychiatric help on a nonurgent basis; therefore, the emergency evaluation becomes the only way to engage them in an extensive psychiatric treatment program.

LIFE-THREATENING EMERGENCIES

Suicidal Behavior

Assessment. Suicidal behavior is the most common reason for an emergency evaluation in adolescents. Despite the minimal risk for a complete suicide in a child less than 12 years of age, suicidal ideation or behavior in a child of any age must be carefully evaluated, with particular attention to the psychiatric status of the child and the ability of the family or the guardians to provide the appropriate supervision. The assessment must determine the circumstances of the suicidal ideation or behavior, its lethality, and the persistence of the suicidal intention. An evaluation of the family’s sensitivity, supportiveness, and competence must be done to assess their ability to monitor the child’s suicidal potential. Ultimately, during the course of an emergency evaluation, the psychiatrist must decide whether the child may return home to a safe environment and receive outpatient follow-up care or whether hospitalization is necessary. A psychiatric history, a mental status examination, and an assessment of family functioning help establish the general level of risk.

Management. When self-injurious behavior has occurred, the adolescent likely requires hospitalization in a pediatric unit for treatment of the injury or for the observation of medical sequelae after a toxic ingestion. If the adolescent is medically clear, the psychiatrist must decide whether the adolescent needs psychiatric admission. If the patient persists in suicidal ideation and shows signs of psychosis, severe depression (including hopelessness), or marked ambivalence about suicide, psychiatric admission is indicated. An adolescent who is taking drugs or alcohol should not be released until an assessment can be done when the patient is in a nonintoxicated state. Patients with high-risk profiles—such as late-adolescent males, especially those with substance abuse and aggressive behavior disorders, and those who have severe depression or who have made prior suicide attempts, particularly with lethal weapons—warrant hospitalization. Young children who have made suicide attempts, even when the attempt had a low
lethality, need psychiatric admission if the family is so chaotic, dysfunctional, and incompetent that follow-up treatment is unlikely.

**Violent Behavior and Tantrums**

**Assessment.** The first task in an emergency evaluation of a violent child or adolescent is to make sure that both the child and the staff members are physically protected so that nobody gets hurt. If the child appears to be calming down in the emergency area, the clinician may indicate to the child that it would be helpful if the child recounted what happened and may ask whether the child feels in sufficient control to do so. If the child agrees and the clinician judges the child to be in good control, the clinician may approach the child with the appropriate backup close at hand. If not, the clinician may either give the child several minutes to calm down before reassessing the situation or, with an adolescent, suggest that a medication may help the adolescent relax.

If the adolescent is clearly combative, physical restraint may be necessary before anything else is attempted. Some rageful children and adolescents brought to an emergency setting by overwhelmed families are able to regain control of themselves without the use of physical or pharmacological restraint. Children and adolescents are most likely to calm down if approached calmly in a nonthreatening manner and given a chance to tell their side of the story to a nonjudgmental adult. At this time, the psychiatrist should look for any underlying psychiatric disorder that may be mediating the aggression. The psychiatrist should speak to family members and others who have been witnessing the episode to understand the context in which it occurred and the extent to which the child has been out of control.

**Management.** Prepubertal children, in the absence of major psychiatric illness, rarely require medication to keep them safe, because they are generally small enough to be physically restrained if they begin to hurt themselves or others. It is not immediately necessary to administer medication to a child or an adolescent who was in a rage but is in a calm state when examined. Adolescents and older children who are assaultive, extremely agitated, or overtly self-injurious and who may be difficult to subdue physically may require medication before a dialogue can take place.

Children who have a history of repeated, self-limited, severe tantrums may not require admission to a hospital if they are able to calm down during the course of the evaluation. Yet the pattern, no doubt, will reoccur unless ongoing outpatient treatment for the child and the family is arranged. For adolescents who continue to pose a danger to themselves or others during the evaluation period, admission to a hospital is necessary.

**Fire Setting**

**Assessment.** A sense of emergency and panic often surrounds the parents of a child who has set a fire. Parents or teachers often request an emergency evaluation, even for a very young child who has accidentally lit a fire. Many children, during the course of normal development, become interested in fire, but in most cases, a school-aged child who has set a fire has done so accidentally while playing with matches and seeks help to put it out. When a child has a strong interest in playing with matches, the level of...
supervision by family members must be clarified, so that no further accidental fires occur. The clinician must distinguish between a child who accidentally or even impulsively sets a single fire and a child who engages in repeated fire setting with premeditation and subsequently leaves the fire without making any attempt to extinguish it. In repeated fire setting, the risk is obviously greater than in a single occurrence, and the psychiatrist must determine whether underlying psychopathology exists in the child or in the family members. The psychiatrist should also evaluate family interactions, because any factors that interfere with effective supervision and communication—such as high levels of marital discord and harsh, punitive parenting styles—can impede appropriate intervention.

Fire setting is one of a triad of symptoms—enuresis, cruelty to animals, and fire setting—that were believed, some years ago, to be typical of children with conduct disorders; however, no evidence indicates that the three symptoms are truly linked, although conduct disorder is the most frequent psychiatric disorder that occurs with pathological fire setting.

**Management.** The critical component of management and treatment for fire setters is to prevent further incidents while treating any underlying psychopathology. In general, fire setting alone is not an indication for hospitalization, unless a continued direct threat exists that the patient will set another fire. The parents of children with a pattern of fire setting must be emphatically counseled that the child must not be left alone at home and should never be left to take care of younger siblings without direct adult supervision. Children who exhibit a pattern of concurrent aggressive behaviors and other forms of destructive behavior are likely to have a poor outcome. Outpatient treatment should be arranged for children who repeatedly set fires. Behavioral techniques that involve both the child and the family are helpful in decreasing the risk for further fire setting, as is positive reinforcement for alternate behaviors.

**Child Abuse: Physical and Sexual**

**Assessment.** Physical and sexual abuse occurs in girls and boys of all ages, in all ethnic groups, and at all socioeconomic levels. The abuses vary widely with respect to severity and duration, but any form of continued abuse constitutes an emergency situation for a child. No single psychiatric syndrome is a sine qua non of physical or sexual abuse, but fear, guilt, anxiety, depression, and ambivalence regarding disclosure commonly surround the child who has been abused.

Young children who are being sexually abused may exhibit precocious sexual behavior with peers and present a detailed sexual knowledge that reflects exposure beyond their developmental level. Children who endure sexual or physical abuse often display sadistic and aggressive behaviors themselves. Children who are abused in any manner are likely to have been threatened with severe and frightening consequences by the perpetrator if they reveal the situation to anyone. Frequently, an abused child who is victimized by a family member is placed in the irreconcilable position of having either to endure continued abuse silently or to defy the abuser by disclosing the experiences and be responsible for destroying the family and risk being disbelieved or abandoned by the family.

In cases of suspected abuse, the child and other family members must be interviewed individually to give each member
a chance to speak privately. If possible, the clinician should observe the child with each parent individually to get a sense of the spontaneity, warmth, fear, anxiety, or other prominent features of the relationships. One observation is generally not sufficient to make a final judgment about the family relationship, however; abused children almost always have mixed emotions toward abusive parents.

Physical indicators of sexual abuse in children include sexually transmitted diseases (e.g., gonorrhea); pain, irritation, and itching of the genitalia and the urinary tract; and discomfort while sitting and walking. In many instances of suspected sexual abuse, however, physical evidence is not present. Thus, a careful history is essential. The physician should speak directly about the issues without leading the child in any direction, because already frightened children may be easily influenced to endorse what they think the examiner wants to hear. Furthermore, children who have been abused often retract all or part of what has been disclosed during the course of an interview.

The use of anatomically correct dolls in the assessment of sexual abuse can help the child identify body parts and show what has happened, but no conclusive evidence supports sexual play with dolls as a means of validating abuse.

**Neglect: Failure to Thrive**

**Assessment.** In child neglect, a child’s physical, mental, or emotional condition has been impaired because of the inability of a parent or caretaker to provide adequate food, shelter, education, or supervision. Similar to abuse, any form of continued neglect is an emergency situation for the child. Parents who neglect their children range widely and may include parents who are very young and ignorant about the emotional and concrete needs of a child, parents with depression and significant passivity, substance-abusing parents, and parents with a variety of incapacitating mental illnesses.

In its extreme form, neglect can contribute to failure to thrive—that is, an infant, usually under 1 year of age, becomes malnourished in the absence of an organic cause ([Figs. 23.3-1 and 23.3-2](#)). Failure to thrive typically occurs under circumstances in which adequate nourishment is available, but a disturbance within the relationship between the caretaker and the child results in a child who does not eat sufficiently to grow and develop. A negative pattern may exist between the mother and the child in which the child refuses feedings and the mother feels rejected and eventually withdraws. She may then avoid offering food as frequently as the infant needs it. Observation of the mother and the child together may reveal a nonspontaneous, tense interaction, with withdrawal on both sides, resulting in a seeming apathy in the mother. Both the mother and the child may seem depressed.
FIGURE 23.3-1

FIGURE 23.3-2
The same infant as in Figure 23.3-1, 3 weeks later, after hospitalization. (Courtesy of Barbon Schmitt, M.D., Children’s Hospital, Denver, CO.)
A rare form of failure to thrive in children who are at least several years old and are not necessarily malnourished is the syndrome of psychosocial dwarfism. In that syndrome, marked growth retardation and delayed epiphyseal malnutrition accompany a disturbed relationship between the parent and the child, along with bizarre social and eating behaviors in the child. Those behaviors sometimes include eating from garbage cans, drinking toilet water, binging and vomiting, and diminished outward response to pain. Half of the children with the syndrome have decreased growth hormone. Once the children are removed from the troubled environment and placed in another setting, such as a psychiatric hospital with appropriate supervision and guidance regarding meals, the endocrine abnormalities normalize, and the children begin to grow at a more rapid rate.

**Management.** In cases of child neglect, as with physical and sexual abuse, the most important decision to be made during the initial evaluation is whether the child is safe in the home environment. Whenever neglect is suspected, it must be reported to the local child protective service agency. In mild cases, the decision to refer the family for outpatient services, as opposed to hospitalizing the child, depends on the clinician’s conviction that the family is cooperative and willing to be educated and to enter into treatment and that the child is not in danger. Before a neglected child is released from an emergency setting, a follow-up appointment must be made.

Education for the family must begin during the evaluation; the family must be told, in a nonthreatening manner, that failure to thrive can become life-threatening, that the entire family needs to monitor the child’s progress, and that they will receive some help in overcoming the many possible obstacles interfering with the child’s emotional and physical well-being.

**Anorexia Nervosa**

Anorexia nervosa occurs in females about ten times as often as in males. It is characterized by the refusal to maintain body weight, leading to a weight at least 15 percent below the expected weight, by a distorted body image, by a persistent fear of becoming fat, and by the absence of at least three menstrual cycles. The disorder usually begins after puberty, but it has occurred in children of 9 to 10 years of age, in whom expected weight gain does not occur, rather than a loss of 15 percent of body weight. The disorder reaches medical emergency proportions when the weight loss approaches 30 percent of body weight or when metabolic disturbances become severe. Hospitalization then becomes necessary to control the ongoing process of starvation, potential dehydration, and the medical complications of starvation, including electrolyte imbalances, cardiac arrhythmias, and hormonal changes.

**Acquired Immune Deficiency Syndrome**

**Assessment.** Acquired immune deficiency syndrome (AIDS), which is caused by the human immunodeficiency virus (HIV), occurs in neonate through perinatal transmission from an infected mother, in children and adolescents secondary to sexual abuse by an infected person, and in adolescents through intravenous drug abuse with an infected person or through intravenous drug abuse with infected needles and through sexual activities with infected partners. Child and adolescent hemophiliac patients may contract AIDS through tainted blood transfusions.

Children and adolescents may present for emergency evaluations at the urging of a family member of a peer; in some
cases, they take the initiative themselves when they are faced with anxiety or panic about high-risk behavior. Early screening of high-risk persons may lead to the treatment of asymptomatic infected patients with such drugs as azidothymidine (AZT) and possibly other new medications that may slow the course of the disease. During the assessment of the risks for HIV infection, an educational process can be initiated with both the patient and the rest of the family so that an adolescent who is not infected, but exhibits high-risk behavior, can be counseled about that behavior and about safe-sex practices.

In children, the brain is often a primary site for HIV infection; encephalitis, decreased brain development, and such neuropsychiatric symptoms as impairment in memory, concentration, and attention span may be present before the diagnosis is made. The virus can be present in the cerebrospinal fluid before it shows up in the bloodstream. Changes in cognitive function, frontal lobe disinhibition, social withdrawal, slowed information processing, and apathy constitute some common symptoms of the AIDS dementia complex. Organic mood disorders, organic personality disorder, and frank psychosis can also occur in patients infected with HIV.

**URGENT NON–LIFE-THREATENING SITUATIONS**

**School Refusal**

**Assessment.** Refusal to go to school may occur in a young child who is first entering school or in an older child or adolescent who is making a transition into a new grade or school, or it may emerge in a vulnerable child without an obvious external stressor. In any case, school refusal requires immediate intervention, because the longer the dysfunctional pattern continues, the more difficult it is to interrupt.

School refusal is generally associated with separation anxiety, in which the child’s distress is related to the consequences of being separated from the parent, so the child resists going to school. School refusal can also occur in children with school phobia, in which the fear and the distress are targeted on the school itself. In either case, a serious disruption of the child’s life occurs. Although mild separation anxiety is universal, particularly among very young children who are first facing school, treatment is required when a child actually cannot attend school. Severe psychopathology, including anxiety and depressive disorders, is often present when school refusal occurs for the first time in an adolescent. Children with separation anxiety disorder typically present extreme worries that catastrophic events will befall their mothers, attachment, or themselves as a result of the separation. Children with separation anxiety disorder may also exhibit many other fears and symptoms of depression, including such somatic complaints such as headaches, stomachaches, and nausea. Severe tantrums and desperate pleas may ensue when preoccupation that a parent will be harmed during the separation is frequently verbalized; in adolescents, the stated reasons for refusing to go to school are often physical complaints.

As part of an urgent assessment, the psychiatrist must ascertain the duration of the patient’s absence from school and must assess the parents’ ability to participate in a treatment plan that will undoubtedly involve firm parental guidelines to ensure the child’s return to school. The parents of a child with separation anxiety disorder often exhibit excessive separation anxiety or other anxiety disorders themselves, thereby compounding the child’s problem. When the parents are unable to participate in a treatment program from home, hospitalization should be considered.

**Management.** When school refusal caused by separation anxiety is identified during an emergency evaluation, the underlying disorder can be explained to the family, and an intervention can be started immediately. In severe cases, however, a multidimensional, long-term family-oriented treatment plan is necessary. Whenever
possible, a separation-anxious child should be brought back to school the next school day, despite the distress, and a contact person within the school (counselor, guidance counselor, or teacher) should be involved to help the child stay in school while praising the child for tolerating the school situation.

When school refusal has been going on for months or years or when the family members are unable to cooperate, a treatment program to move the child back to school from the hospital should be considered. When the child’s anxiety is not diminished by behavioral methods alone, tricyclic antidepressants, such as imipramine (Tofranil), are helpful. Medication is generally prescribed not at the initial evaluation but after a behavioral intervention has been tried.

**Munchausen Syndrome by Proxy**

**Assessment.** Munchausen syndrome by proxy, essentially, is a form of child abuse in which a parent, usually the mother, or a caretaker repeatedly fabricates or actually inflicts injury or illness in a child for whom medical intervention is then sought, often in an emergency setting. Although it is a rare scenario, mothers who inflict injury often have some prior knowledge of medicine, leading to sophisticated symptoms; the mothers sometimes engage in inappropriate camaraderie with the medical staff regarding the treatment of the child. Careful observation may reveal that the mothers often do not exhibit appropriate signs of distress on hearing the details of the child’s medical symptoms. Prototypically, such mothers tend to present themselves as highly accomplished professionals in ways that seem inflated or blatantly untrue.

The illnesses appearing in the child can involve any organ system, but certain symptoms are commonly presented: bleeding from one or may sites, including the gastrointestinal (GI) tract, the genitourinary system, and the respiratory system; seizures; and central nervous system (CNS) depression. At times, the illness is simulated, rather than actually inflicted.

**OTHER CHILDHOOD DISTURBANCES**

**Posttraumatic Stress Disorder**

Children who have been subjected to a severe catastrophic or traumatic event may present for a prompt evaluation because they have extreme fears of the specific trauma occurring again or sudden discomfort with familiar places, people, or situations that previously did not evoke anxiety. Within weeks of a traumatic event, a child may re-create the event in play, in stories, and in dreams that directly replay the terrifying situation. A sense of reliving the experience may occur, including hallucinations and flashback (dissociative) experiences, and intrusive memories of the event come and go. Many traumatized children, over time, go on to reproduce parts of the event through their own victimization behaviors toward others, without being aware that those behaviors reflect their own traumatic experiences.

**Dissociative Disorders**

Dissociative states—including the extreme form, multiple personality disorder—are believed most likely to occur in children who have been subjected to severe and repetitive physical, sexual, or emotional abuse. Children with dissociative symptoms may be referred for evaluation because family members or teachers observe that the children sometimes seem
to be spaced out or distracted or act like different persons. Dissociative states are occasionally identified during the
evaluation of violent and aggressive behavior, particularly in patients who truly do not remember chunks of their own
behavior.

When a child who dissociates is violent or self-destructive or endangers others, hospitalization is necessary. A variety of
psychotherapy methods have been used in the complex treatment of children with dissociative disorders, including play
techniques and, in some cases, hypnosis.

Complementary and Alternative Medicine in Psychiatry

The science and art of “healing” as well as the concept of “illness” have always been significantly influenced by the cultural context in which they developed. What most Western medical practitioners conceive of as “health care” is actually quite in its infancy compared with many practices aimed at curing or ameliorating illness that developed across the world for many centuries past. Major advances in biomedical research and in the scientific method in general over the past century have brought that discovery of revolutionary medical interventions that have saved countless lives, most notably through the treatment of infectious illnesses. Yet, many practitioners and patients alike sense that the biological and reductionist concepts of illness and its treatment that have come to guide much of Western medical care often minimize the role of psychosocial factors in health and wellness. Psychiatry itself, supposed champion among medical fields in addressing psychosocial etiologies of illness, has also become increasingly biological in its focus. Although this approach has undoubtedly benefited persons with mental illness and has increased public awareness that the brain is no less a physical organ than the heart or kidney (susceptible to maladies at times through no fault of the person suffering mental illness), some mental health practitioners worry that the “listening care” in psychiatry will become increasingly marginalized. After all, addressing psychosocial aspects of health is almost always more time-consuming than biological interventions and thus, in a short-sighted vision of health outcomes, often seems inefficient and expensive.

The term complementary and alternative medicine (CAM) refers to the various disease-treating or disease-preventing practices whose methods and efficacies differ from traditional or conventional biomedical treatment. Other terms used to describe these therapeutic approaches are integrative medicine and holistic medicine. This is not a new concept in psychiatry. The idea of emphasizing the whole patient and the need to evaluate psychosocial, environmental, and lifestyle factors in health and disease is subsumed under the heading of psychosomatic or mind-body medicine.

Traditional medicine, as practiced in the United States and elsewhere in the Western world, is based on the scientific method—the use of experiments to validate a hypothesis or determine the probability of a theory being correct. Traditional medicine presumes that the body is a biological and physiological system and that disorders have a cause that can be treated with medications, surgery, and complex technological methods to produce a cure. Traditional medicine is thus also referred to as biomedicine or technomedicine.

Traditional medicine is also known as allopathic medicine. The term allopathy, derived from the Greek word allos (“other”), refers to the use of outside agents or medications to counteract the signs and symptoms of disease; for example, antipyretics to treat fever. Allopathy is the type of medicine taught in medical schools in the United States. Samuel
Hahnemann (1755–1843), a German physician, coined the term to distinguish this form of medicine from *homeopathy* (derived from the Greek word *homos* [“same”]), in which specially formulated medicinal remedies, different from allopathic medicine, are used. Allopathy is the most prevalent form of medicine practiced in the Western world. (Homeopathy is discussed more fully later in this chapter.)

**NATIONAL CENTER FOR COMPLEMENTARY MEDICINE AND ALTERNATIVE MEDICINE**

The widespread adoption of CAM practices led the US government to establish the National Center for Complementary Medicine and Alternative Medicine (NCCAM) within the National Institutes of Health (NIH). NCCAM’s mission is to evaluate the usefulness and safety of a broad range of unrelated, nonorthodox healing practices and provide scientific explanations for their possible effectiveness, train CAM researchers, and disseminate information to the public. NCCAM has proposed changing its name to the National Center for Research on Complementary and Integrative Health Care (NCRCI).

An NCCAM study in 2011 revealed that close to 40 percent of Americans used some form of CAM within a 12-month period. When prayer was included, the percentage rose to more than 60 percent. Prayer for one’s own health was most prominent, followed by prayer by others for one’s own health, natural products, deep-breathing exercises, group prayer, meditation, chiropractic care, yoga, massage, and diet-based therapies. Echinacea, ginseng, Ginkgo biloba, garlic supplements, glucosamine, and St. John’s wort were among the most common natural products used. Back, head, and neck pain were the most common conditions treated. The CAM practices were most likely to be embraced by those with more education, women, former smokers, and those who had been recently hospitalized. Most users of CAM practices believed the greatest benefits were achieved in combination with conventional treatment.

NCCAM conducts clinical trials at the NIH and academic research institutions to investigate the benefits of various CAM practices on a spectrum of diseases and disorders, ranging from psychiatric conditions to cancer, osteoporosis, and multiple sclerosis, among others. Some completed studies have validated the following: acupuncture is beneficial to treat functional impairment and osteoarthritic pain of the knee; no prophylactic benefit was found for low-dose *Echinacea augustifolia* in the prevention of cold symptoms; combined glucosamine and chondroitin sulfate supplements do not provide significant relief for osteoarthritic pain in most cases, but does benefit a smaller subset with more severe pain; and St. John’s wort (*Hypericum perforatum*) is no more effective for treating major depression of moderate severity than placebo. St. John’s wort is being further investigated as a treatment for posttraumatic stress disorder (PTSD), anxiety, and minor depression (see “Herbal Medicine” below).

The NCCAM has compiled a classification of alternative medical practices designed to support research (Table 24-1). Including a practice in the classification does not imply an endorsement of the method. Indeed, many complementary and alternative health practices are based on no known scientific principles and are considered quackery.

| Table 24-1 | Complementary and Alternative Medicine Practices |
Many systems of treatment discussed in this chapter are centuries old, and it would be presumptuous for traditional biomedical practitioners to dismiss them lightly as worthless. Nevertheless, without rigorous scientific evidence to the contrary, physicians must approach many of these treatments with skepticism. The influence of the mind on the body and the effect of psychological factors in health and disease are well known to physicians, especially to psychiatrists. Suggestion is a potent remedy, and the well-established placebo effect, in which an inert substance is effective in curing a disorder, serves to confirm the importance of mind–body interaction in health and disease.

Currently, more than half of the medical schools in the United States offer some form of complementary and alternative medicine education. Several have developed centers for alternative medicine research, with professors of mind–body or integrative medicine drawn largely from the ranks of such traditional specialties as internal medicine and psychiatry. This trend is likely to continue, with the goal of determining which of the many existing alternative medical systems have scientific merit. Only when and if they can withstand rigorous clinical trials can these techniques be integrated into traditional medicine.

Listed below in alphabetical order are some of the most visible complementary and alternative health practices that have been used in the treatment of (broadly defined) psychiatric conditions. The discussion of therapies should not be considered definitive; new therapies continue to emerge. The number of alternative healing practices available in the United States is unknown and probably soars into the hundreds and their practitioners into the tens of thousands, and there are no national standards set to credential such practitioners.

**ACUPRESSURE AND ACUPUNCTURE**

Acupressure and acupuncture are Chinese healing techniques that are mentioned in ancient medical texts dating back to 5000 B.C. and continue to be an important medical
intervention in the East. A basic tenet of Chinese medicine is the belief that vital energy (\(qi\) or \(chi\)) flows along specific pathways (meridians) that have about 350 major points (acupoints) whose manipulation corrects imbalances by stimulating or removing blockages to energy flow. Another fundamental concept is the idea of two opposing energy fields (\(yin\) and \(yang\)) that must be in balance for health to be sustained. In acupressure, the acupoints are manipulated by the fingers; in acupuncture, sterilized silver or gold needles (some the diameter of a human hair) are inserted into the skin to varying depths (0.5 mm to 1.5 cm) and are rotated or left in place for varying periods to correct any imbalance of \(qi\).

In the West, acupressure and acupuncture are explained on the basis of nerve stimulation that releases endogenous neurotransmitters, endorphins, and enkephalins to help cure illness. The benefits of acupuncture have been validated in a variety of conditions, most notably pain management, postoperative nausea and vomiting, osteoarthritis of the knee, fibromyalgia, and headaches. Other conditions treated with these techniques are asthma, dysmenorrhea, cervical pain, insomnia, anxiety, depression, and substance abuse, including smoking cessation (see the description of moxibustion below). Most pain management clinics in the United Kingdom use acupuncture treatment. A variation of acupuncture, which uses mild electric current to augment therapeutic effects (electroacupuncture), is most often used for analgesia or during surgery. Acupuncture applied to the ear (auriculocupuncture) is also common.

ALEXANDER TECHNIQUE

The Alexander technique was developed by F. M. Alexander (1869–1955), who was born in Tasmania and eventually became a well-known stage actor. After developing aphonia, he experimented on himself by changing his body posture and eventually regained his voice. Alexander developed a theory of the proper use of body musculature to help alleviate somatic and mental illnesses. Alexander’s approach is an educational process that reduces habitual, unnecessary muscular tension in everyday movements (i.e., unintentionally straining the neck while sitting at a computer) by improving sensory awareness and conscious control of these maladaptive physical habits (Fig. 24-1). Treatment improves cardiovascular, respiratory, and gastrointestinal functioning as well as mood. A small, devoted group of Alexander practitioners is found in the United States and throughout the world. The Alexander technique holds promise as an approach to pain management; it has been shown to be effective in treating chronic back pain in several recent independent studies (Fig. 24-1).
ANTHROPOSOPHICALLY EXTENDED MEDICINE

Anthroposophically extended medicine is a form of healing developed by the Austrian philosopher Rudolf Steiner (1861–1925). The healing process involves the use of conscious understanding, which Steiner called anthroposophy, or the “wisdom of life.” Anthroposophy focuses on mental exercises that enable persons to find a balance between mind and body to ensure health maintenance. Steiner founded a school of thought represented in this country by the Rudolf Steiner School, which teaches children these concepts as they apply to civilization, besides a standard educational curriculum.

AROMATHERAPY

Aromatherapy is the therapeutic use of plant oils. Named by the French chemist Maurice René-Maurice Gattefossé in 1928, aromatherapy is one of the fastest growing alternative therapies in the United States and Europe. The essential oils of plants are organic compounds that are benzene derivatives. Aromatic substances were used in ancient civilization as both medicines and perfumes. Today, plant oils are inhaled using atomizers or are absorbed through the skin using massage (aromatherapy massage). Plant oils have many therapeutic effects—analgesic, psychological, antimicrobial—one of which have been demonstrated scientifically. One NCCAM study, for example, found the scent of lavender helped promote sleep. Aromatherapy is used to reduce stress and anxiety and to alleviate gastrointestinal and musculoskeletal disorders. In psychiatry, olfactory stimulation has been used to elicit feeling tones, memories, and emotions during psychotherapy. Aromatherapy can cause skin irritation or allergic reactions in
some people. Table 24-2 lists the essential oils and their effects.

(Table by Marissa Kaminsky, M.D.)

Pheromones are chemical substances secreted and smelled by humans, which affect their physiological and behavioral responses, usually related to sex. Women who are exposed to the smell of androstenol, which occurs in male underarm sweat, show increased social exchanges with men, heightened sexual arousal, and improved mood. Androstenol also affects the length and timing of the menstrual cycle as a result of changes in the level and release of gonadotrophic-releasing hormone (GnRH) and luteinizing hormone (LH). Female pheromones, known as copulins, are present in female underarm sweat and in vaginal secretions. Males perceive the odor of copulins as most pleasant during the woman’s ovulatory cycle when such odors are most volatile. The synchronization of the menstrual cycle of women living together (a well-documented phenomenon) is also related to the effect of copulins. Olfactory sexual signaling is being investigated extensively, and whether these studies show therapeutic potential remains to be seen.
AYURVEDA

Ayurveda means “knowledge of life.” The technique originated in India about 3000 B.C. and is believed to be one of the oldest and most comprehensive medical systems in the world. Ayurveda is similar to Chinese medicine in its beliefs about energy points on the body and a vital force (prana) that must be in balance to maintain health. Ayurveda practitioners diagnose illness by examining the pulse, the urine, and the heat or coldness of the body. Treatment relies on diet, medicines, purification, enemas, and bloodletting. (See also “Tibetan Medicine” below.)

BATES METHOD

The Bates method, designed to treat vision problems, was devised by William H. Bates. It is aimed at naturally strengthening the eye muscles and includes the following basic exercises: splashing closed eyes 20 times with warm water, then 20 times with cold water; alternately focusing on near and distant objects; focusing on an object while gently swaying the body; remembering objects in the mind’s eye to facilitate the actual perception of these objects in reality; and closing the eyes, cupping them with the palms of both hands (without touching the eyes), and focusing on pleasant thoughts. Bates practitioners claim that persons who need glasses to correct refraction errors will not need them if these methods are followed rigorously.

BIOENERGETICS

Bioenergetics, based on the belief that dammed-up energy produces maladaptive behavioral patterns, evolved from the work of the Austrian psychoanalyst Wilhelm Reich (1897–1957), who studied with Sigmund Freud. Reich believed that energy fields were propelled by sexual impulses called ergs and that satisfactory orgasms indicated healthy bodily functioning. Modern-day practitioners look for areas of muscular tension in the body that are thought to be associated with repressed memories and emotions. Therapists try to bring these repressions to consciousness through a variety of relaxation techniques, including massage.

CHELATION

Chelation therapy is a traditional medical procedure used to treat accidental poisoning with heavy metals, such as lead, arsenic, and mercury. A chelating agent (ethylenediaminetetraacetic acid [EDTA]) is infused into the bloodstream and binds to the metal, which is then excreted from the body. As an alternative medical practice, chelation therapy is used as a form of preventive medicine to remove lead, cadmium, and aluminum from the body. These substances are presumed by some to be associated with premature aging, memory loss, and the symptoms of Alzheimer’s disease. Chelation therapy has also been used to treat atherosclerosis and coronary artery disease. One NCCAM study showed that chelation treatments reduced cardiovascular events such as
heart attacks and death in patients with diabetes; however, chelation therapy is not yet approved by the U.S. Food and Drug Administration (FDA) as a treatment for this condition.

CHIROPRACTIC

Chiropractic is concerned with the diagnosis and treatment of disorders of the musculoskeletal system, especially those of the spine. It was developed by a Canadian, Daniel David Palmer (1845–1913) (Fig. 24-2), who moved to the United States in 1895. Palmer believed that disease could be attributed to spinal misalignment, leading to abnormal nerve transmission.

![Daniel David Palmer (1845–1913), the founder of chiropractic.](https://www.shealybooks.com/complete FAMILY GUIDE TO ALTERNATIVE MEDICINE/fig4.jpg)

Chiropractors diagnose illness by clinical examination and X-ray. Treatment involves manual manipulation of bones, joints, and musculature to restore biomechanical function. Chiropractic is the largest independent alternative health profession in the Western world, with more than 50,000 chiropractors in the United States. They are recognized by government and insurance agencies and treat more than 20 million persons in the United States annually.

COLONIC IRRIGATION

Colonic irrigation is a technique known since antiquity that consists of flushing the intestinal colon with large quantities of water, sometimes with minerals or other substances (e.g., coffee) added. It is a method used to eliminate autointoxication, a concept originating from the Pasteur Institute in France in 1908 that holds that retained fecal matter and undigested food ferment in the bowel producing toxins that cause
Special colon hydrotherapy machines force fluids via the rectum to clean the colon of this matter, thus eliminating such toxins. Colon cleansing using powerful laxatives and enemas is an alternative way of achieving the same result. Anecdotal reports of improved general health as a result of such practices are common; however, there are risks of electrolyte imbalance and intestinal perforation. The practice is poorly regulated, although some states attempt to monitor therapists and equipment.

COLOR THERAPY

In color therapy, different colors are thought to affect mood, and this has been used to address specific health problems. For example, blue is believed to be sedating, and red, excitatory. A Swiss psychologist, Max Lüscher, devised a color test in which a subject’s mood at a particular time is determined by exposing the subject to various colors. Lüscher also experimented with the effect of color on the autonomic nervous system and found that pure red is sympathomimetic and can cause an increase in blood pressure, heart rate, and respiration. Blue is parasympathomimetic and produces the opposite effects.

DANCE THERAPY

Dance therapy was formally recognized in 1942, with the hiring of pioneer dance therapist Marian Chace (1896–1970) at St. Elisabeth’s Hospital in Washington, D.C. The terms dance and movement are used synonymously; however, each actually describes a point of view. Movement encompasses the world of physical motion, whereas dance is a specific creative act within that world. The American Dance Therapy Association defines dance therapy as “the psychotherapeutic use of movement which furthers the emotional and physical integration of the individual.” Dance therapy sessions have four basic goals: the development of body awareness; the expression of feelings; the fostering of interaction and communication; and the integration of the physical, emotional, and social experiences that result in a sense of increased self-confidence and contentment.

DIET AND NUTRITION

Nutritional methods to prevent or cure disease have an important place in modern medicine, and their efficacy has been proved by scientific evidence. The federal government has established recommended daily allowances (RDAs) to meet the nutritional needs of average persons in the United States. Table 24-3 depicts the recommendations for a 40-year-old sedentary man. Whole grain, lean meat, and green vegetable consumption are encouraged, and excess intake of unrefined sugar products is discouraged. Critics have faulted the federal guidelines for being unduly influenced by the meat and dairy industries. Nutritional experts and dieticians have developed alternate recommendations, especially for children, adolescents, diabetics, and pregnant women.
Many alternative diets exist, and specific vitamin and mineral supplementation programs have been developed to deal with specific diseases or bodily processes. Diets low in fat have been recommended for the treatment of cardiovascular disease and diabetes. The Pritikin diet developed by Nathan Pritikin is extremely low in fat (less than 10 percent of daily calories), high in complex carbohydrates, and high in fiber. The Ornish diet, developed by physician Dean Ornish, is vegetarian: No meat, poultry, or fish is allowed, and only 10 percent of calories are obtained from fat. The low carbohydrate, high protein diet developed by Robert Atkins, M.D. (1930–2003) has proved effective in short-term weight loss, most likely because of increased compliance. Concern exists around the risk of ketoacidosis and the lack of long-term studies on health. This diet has also been used to treat refractory childhood epilepsy. All of these diets include an exercise program, a component proved to increase cardiac performance. Studies have shown that weight loss alone can reduce cholesterol, decrease blood pressure, and eliminate the need for drugs in newly diagnosed cases of adult-onset diabetes.

Diets from other cultures may have certain health benefits. In Asia, diets are low in fat, and there is a low incidence of cardiac disease; diets in Mediterranean countries are high in olive oil, garlic, and grains and are associated with a low incidence of colon cancer and cardiac disease. Food allergies have been implicated in many conditions: arthritis, asthma, hyperactivity, and ulcerative colitis, among others.

**DIETARY SUPPLEMENTS**

In addition to herbs (discussed below), a variety of dietary supplements are used to promote health. Dietary supplements are products that contain vitamins, minerals, or amino acids. In many cases, the supplement is actually an extract, metabolite, or combination of those. They are intended to *supplement* a healthy diet; they do not comprise a diet or meal. Nutritional supplements have long been familiar to Americans in the form of multivitamins, but they are now available in a vast array of other...
compounds that can be purchased in grocery stores, pharmacies, health food stores, and over the Internet. Annual sales of dietary supplements in the United States exceed $20 billion. Of Americans, 75 percent currently use some form of nutritional supplement on a regular basis. Although medicinal benefits are well documented in some supplements, especially vitamins, others vary greatly in safety and consistency. As a general rule, supplements should not be taken by pregnant or lactating women. In psychiatry, nutritional supplements are being used to treat a wide spectrum of illness including cognitive, mood, psychotic, sleep, and conduct disorders; however, little scientific evidence currently supports their efficacy. Table 24-4 lists some of the more common supplements being used to treat psychiatric illness.

</table>

(continued)
| **5-Hydroxytryptophan (5-HTP)** | Immediate precursor of serotonin | Depression, obesity, insomnia, fibromyalgia, headaches | Possible risk of serotonin syndrome in those with carcinoid tumors or taking MAOIs | SSRIs, MAOIs, methylxanthines, St. John's wort, peroxynitrite, 5-HT antagonists, 5-HT receptor antagonists | 100 mg-2 g daily, safer with carbidopa | 5-HTP along with carbidopa is used in Europe for the treatment of depression |
| Phenylalanine | Essential amino acid | Depression, analgesia, vitiligo | Contraindicated in patients with PKU, may exacerbate tardive dyskinesia or hypertension | MAOIs and neuroleptic drugs | Comes in 2 forms: 500 mg-1.5 g daily for α-phenylalanine, 375 mg-2.25 g for oxphenylalanine | Found in vegetables, juices, yogurt, and miso |
| Myo-inositol | Major nutritionally active form of inositol | Depression, panic attacks, OCD | Caution in patients with bipolar disorder, GI distress | Possible additive effects with SSRIs and 5-HT receptor agonists (sumatriptan) | 12 g in divided doses for depression and panic attacks | Studies have not shown effectiveness in treating Alzheimer's disease, autism, or schizophrenia |
| Vinpocetine | Semisynthetic derivative of vincamine (plant derivative) | Cerebral ischemic stroke, dementias | GI distress, dizziness, insomnia, dry mouth, tachycardia, hypotension, flushing | Warfarin | 5-10 mg daily with food, no more than 20 mg per day | Used in Europe, Mexico, and Japan as a pharmaceutical agent for treatment of cerebrovascular and cognitive disorders |
| Vitamin E family | Essential fat-soluble vitamin, family made of tocopherols and tocotrienols | Immune-enhancing, antioxidant, some cancers, protection in CV disease, neurologic disorders, diabetes, premenstrual syndrome | May increase bleeding in those with propensity to bleed, possible increased risk of hemorrhagic stroke, thrombembolism | Warfarin, antiplatelet drugs, neomyein, may be additive with statins | Depends on form: tocotrienols, 200-300 mg daily with food; tocopherol, 200 mg per day | Stop members of vitamin E family 1 month prior to surgical procedures |
| Glycine | Amino acid | Schizophrenia, alleviating spasticity and seizures | Avoid in those who are anuric or have hepatic failure | Additive with antispasmodics | | |
| Melatonin | Hormone of pineal gland | Insomnia, sleep disturbances, jet lag, cancer | May inhibit ovulation in 1 g doses, seizures, giddiness, depression, headache, amnesia | Aspirin, NSAIDs, β-blockers, INH, sedating drugs, corticosteroids, valerian, kava kava, 5-HTP, alcohol | 0.3-3 mg hs for short periods of time | Melatonin sets the timing of circadian rhythms and regulates seasonal responses |
| Fish oil | Lipids found in fish | Bipolar disorder, lowering triglycerides, hypertension, decreased blood clotting | Caution in hemophilias, mild GI upset, "fishy" smelling excretions | Coumarin, aspirin, NSAIDs, garlic, gingko | Varies depending on form and indication—usually about 3-5 g daily | Stop prior to any surgical procedure |

ADD: attention-deficit disorder; CV: cardiovascular; OCD: obsessive-compulsive disorder; GI: gastrointestinal; MAOIs: monoamine oxidase inhibitors; PKU: phenylketonuria; SSRIs: selective serotonin reuptake inhibitors; NSAIDs: nonsteroidal anti-inflammatory drugs; INH: isoniazid; 5-HT: 5-hydroxytryptophan.

(Table by Mercedes Blackstone, M.D.)
Nutritional status has long been deemed important in mental health, and vitamin deficiencies can produce psychiatric symptoms. Severe niacin deficiency results in pellagra with its characteristic triad of skin lesions, gastrointestinal disorders, and psychiatric symptoms. The psychiatric symptoms include irritability and emotional instability progressing to severe depression and then to disorientation, memory impairment, hallucinations, and paranoia. Folic acid deficiency is associated with depression and dementia, whereas vitamin B₁₂ deficiency is associated with cognitive impairment, depression, and other affective symptoms. Severe malnutrition can result in apathy and emotional instability.

In 1968, the eminent chemist and Nobel Prize–winner Linus Pauling coined the term orthomolecular to refer to the connection between the mind and nutrition. In his book *Orthomolecular Psychiatry*, research articles were compiled supporting the notion that taking many times the recommended minimal daily dose of vitamins is useful in the treatment of schizophrenia and other psychiatric disorders. As mentioned, some severe vitamin deficiencies can result in syndromes with a psychiatric component; however, empirical data and an American Psychiatric Association (APA) task force failed to find evidence supporting the notion that schizophrenia and other disorders respond to vitamin therapies.

**Thiamine, Vitamin B₁₂, and Folate**

In industrialized societies, severe vitamin deficiencies are rarely encountered except in certain populations. Those who are elderly, alcohol dependent, or chronically ill or who have certain types of gastrointestinal surgeries are at greatest risk. Among the forms of vitamin deficiency most commonly encountered in the emergency room is acute thiamine depletion from alcohol dependence. Whereas the chronic forms of thiamine deficiency that lead to beriberi are rarely seen in the Western world, the fulminant depletion of already low stores of thiamine results in Wernicke’s encephalopathy and Korsakoff’s syndrome.

Wernicke’s encephalopathy classically presents with the triad of ataxia, ophthalmoplegia, and mental confusion, but confusion and a staggering gait are perhaps most common. Although Wernicke’s encephalopathy is an acute process, Korsakoff’s syndrome may be the permanent residue of this encephalopathy. Patients with Korsakoff’s syndrome exhibit a well-circumscribed retrograde and anterograde amnesia that results from destruction of the mammillary bodies, and psychotic symptoms are also reported. Wernicke’s encephalopathy is a medical emergency that responds to short-term treatment with 50 mg of thiamine intravenously followed by 250-mg intramuscular injections daily until a normal diet is attained. The treatment of uncomplicated acute thiamine deficiencies usually involves 100 mg given orally one to three times a day.

Vitamin B₁₂ deficiency or pernicious anemia is often seen in elderly adults, patients who have had gastric surgery, and malnourished depressed patients. The most typical psychiatric presentations include apathy, malaise, depressed mood, confusion, and memory deficits. Vitamin B₁₂ concentrations of 150 mg/mL of serum are sometimes associated with these symptoms. Vitamin B₁₂ deficiency is a more common cause of reversible dementia and is typically assessed in dementia evaluations. The treatment of pernicious anemia usually involves daily intramuscular injections of 1,000 mg of vitamin B₁₂ for approximately 1 week, followed by maintenance doses of 1,000 mg every 1 to 2 months.

Folate deficiency has been associated with depression, paranoia, psychosis, agitation, and dementia. Folate deficiency can result from anorexia in depressed patients and can also contribute to depression by interfering with the synthesis of norepinephrine and
serotonin. Folate deficiency has been associated with anticonvulsant use, particularly phenytoin (Dilantin), primidone (Mysoline), and phenobarbital (Solfoton), and the sex steroids, including oral contraceptives and estrogen replacement. The most common cause of folate deficiency is the malnourishment associated with alcoholism. Many folate deficiencies respond to 1 mg of folate orally per day; however, some more severe forms may require dosages of 5 mg up to three times a day. Folate deficiency in pregnancy is associated with neural tube defects (e.g., spina bifida, anencephaly).

Mr. S was diagnosed with dysthymic disorder by a psychiatrist in his early 20s and was started on sertraline (Zoloft). After 4 weeks Mr. S’s mood improved dramatically, but he experienced night sweats and reduced libido. Over the ensuing years he was tried on paroxetine (Paxil), citalopram (Celexa), and fluoxetine (Prozac). Although his mood improved, his sex drive did not. Mr. S heard about an integrative mental health clinic that offered conventional medications, herbal medications, acupuncture, and Reiki. Mr. S was interviewed by a Western physician who had also studied Chinese medicine. The Chinese pulse diagnosis of stagnant liver qi was consistent with his Western diagnosis of moderate depressed mood. The doctor ordered a thyroid panel, red blood cell (RBC) folate, and B₁₂ levels and suggested an integrative treatment plan including supplementation with folate, B₁₂, omega-3 fatty acids, and S-Adenosyl-l-methionine (SAMe), regular exercise, and acupuncture. The initial treatment plan consisted of daily exercise, SAMe (titrating to 400 mg twice daily), folate 5 mg, B₁₂ 800 μg, and omega-3s (eicosapentaenoic acid [EPA] 2 g per day). Three weeks later, Mr. S was frustrated at his lack of progress, remained depressed, and had not started to exercise. His RBC folate level was low, and the other studies were within normal limits. Mr. S had been taking an inexpensive generic brand of SAMe and had stayed at 200 mg per day. He was encouraged to follow the original treatment plan. Two weeks later, Mr. S appeared brighter. He was exercising daily and taking the B vitamins and a quality brand of SAMe at 400 mg twice daily without significant adverse effects. (Adapted from James H. Lake, M.D.)

ENVIRONMENTAL MEDICINE

The field of environmental medicine began to emerge in the 1950s when physicians such as Theron Randolf, professor of allergy and immunology at Northwestern University School of Medicine, began to examine some persons’ allergic reactions to various foods. Other workers studied the effects on the body of pollutants in water and air, and eventually the field expanded to include the total environment in which humans exist. As a result, environmental medicine now concerns itself with issues such as food additives; electromagnetic fields from electric utility wires; fertilizers and hormones used in food production; microwaves from appliances such as microwave ovens, television sets, and cellular telephones; and nuclear radiation. Practitioners of environmental
medicine believe that many persons are extraordinarily sensitive to environmental contaminants that can trigger a disease process. Some issues are highly controversial. For instance, despite claims to the contrary, studies fail to demonstrate a higher incidence of cancer in persons exposed to electromagnetic fields; however, a correlation exists between higher cancer rates and living near oil refineries and chemical plants. Environmental medicine is a form of preventative medicine that focuses on increased individual awareness of environmental hazards and the control or elimination of these hazards. (See also “Naturopathy” below.)

EXERCISE

Exercise improves quality of life through better physical function, reduced morbidities, and improved mental health. The positive effects of exercise on immune system functions are well documented. These benefits extend to the cognitive and emotional realms and, thus, validate the mind–body connection that is central to many CAM physical practices—yoga, tai chi, qi gong. Exercise has been shown to ameliorate depression, anxiety, and PTSD; improve cognitive function and self-esteem; and reduce psychotic symptoms in schizophrenic populations. These effects can be accounted for neurochemically, because exercise promotes secretion of neurotransmitters, such as serotonin, adrenaline, and endogenous opiates. Studies have also associated weight loss with increased social interaction, distraction from stress, recreational enjoyment, and mastery of challenge.

Exercise offers many benefits to people with serious mental illness because they more likely suffer from serious medical conditions, such as obesity, diabetes, and hypertension; live sedentary lifestyles; and smoke. Studies of adults with schizophrenia have shown a moderate exercise program reduces body mass index, improves aerobic fitness, raises self-esteem, and results in fewer psychiatric symptoms. Exercise may prove useful in remediating the weight gain from antipsychotic medications and improve compliance.

Although presently underused, exercise holds significant potential benefit as a therapeutic intervention in the mental health care setting. A structured aerobic exercise program consisting of 45-minute sessions three times per week showed significant gains in cardiovascular fitness, self-esteem, and quality of life and in altering mood and depression. Unstructured programs benefited those who adhere to the exercise regimen. No drawbacks are found to moderate exercise, and the health gains are significant.

FELDENKRAIS METHOD

The Feldenkrais method was developed by Moshé Feldenkrais (1904–1984), a Russian-born physicist who developed a theory evolved from Freud’s work. Feldenkrais thought that the body should be emphasized as much as the mind and that proprioception (somatic sensations from muscles and other organs) can influence behavior. He believed that posture and the positions of the body reflected conflict; therefore, retraining the body was part of his treatment program. Practitioners of the Feldenkrais method are active throughout the world. Those learning the Feldenkrais method are referred to as students rather than patients, to reinforce the view that the work is primarily an
educational process. Lessons generally last from 30 to 60 minutes and consist of structured movement that involves thinking, sensing, moving, and imagining. The method has been used in central nervous system disorders, such as multiple sclerosis, cerebral palsy, and stroke. Older persons who use the method claim that they retain or regain their ability to move without strain or discomfort.

HERBAL MEDICINE

Herbal medicine relies on plants to cure illnesses and to maintain health. Probably the oldest known system of medicine, it originated in China about 4000 B.C. Ancient texts of Chinese medicine are still in use, and modern Chinese medicine relies on herbs in addition to other methods, such as acupuncture, massage, diet, and exercise, to correct imbalances in the body. A Greco-Roman medical text by Pedanius Dioscorides, *De Materia Medica*, describes the use of more than 500 plants and herbs to cure disease.

The decline of herbal medicine in the late 20th century was related to scientific and technological advances that led to the use of synthetic pharmaceuticals; nevertheless, according to some estimates, at least 25 percent of current medicines are derived from the active ingredients of plants. The examples are many: digitalis from foxglove; ephedrine from ephedra; morphine from the opium poppy; paclitaxel (Taxol) from the yew tree; and quinine from the bark of the cinchona tree.

Herbal medicine is becoming more and more popular. Approximately $4 billion a year is spent in the United States on herbal medicines, which are classified as dietary supplements. Western herbalists use plants to treat various disorders related to the respiratory, gastrointestinal, cardiovascular, and nervous systems; as with most prescription medicines, these plants contain active compounds that produce physiological effects. As a result, they must be used in appropriate doses if toxic results are to be prevented. They are not subject to FDA approval, and no uniform standards exist for quality control or potency in herbal preparations. Indeed, some preparations have no active ingredients or are adulterated. Herbal supplement producers need only prove safety and truth in labeling, not efficacy, to be sold. The herbal industry attempts to regulate itself through organizations such as the Council for Responsible Nutrition and the American Herbal Association, but according to the Federal Trade Commission, fraudulent practices and false advertising still exist. In 2003, the FDA banned ephedra (ma huang)-based diet products because of significant risk to cardiovascular health. There is now a *Physicians Desk Reference* for both herbal products and nutritional supplements.

One herb that has caught the attention of Western psychiatry is St. John’s wort (*Hypericum*) for the treatment of major depressive disorders (Fig. 24-3). St. John’s wort has been used in folk medicine for hundreds of years and is still commonly used in Europe. In Germany, several million prescriptions for *Hypericum* are obtained annually and covered by insurance for the treatment of depression, anxiety, and sleep problems. Studies have compared St. John’s wort with placebo, tricyclic drugs, and selective serotonin reuptake inhibitors (SSRIs) and found that *Hypericum* extracts were more effective than placebo in the treatment of mild to moderate depression. Many of these studies lacked rigor in the diagnosis of depression, sample size, and the assessment of efficacy. NCCAM sponsored studies and other researchers are working to determine the
Mrs. J, a 68-year-old retired schoolteacher in good health, was experiencing anhedonia after the death of her spouse and was started on a low-dose SSRI by her psychiatrist. After several weeks, her symptoms began to improve. One morning, while at the local health food store, she inquired if there were any natural products that improved mood. The store manager informed her that St. John’s wort “works just like an SSRI.” The patient proceeded to take the recommended daily dose of three capsules that day, each containing 300 mg of 0.3 percent Hypericin. Later that evening, she began to feel anxious and could not fall asleep. After several hours of doing needlework to pass the time, she began to sweat profusely. She became concerned for her health when she felt her heart racing. She drove herself to the emergency room of a local hospital. On examination, she was observed to be extremely anxious and hyperactive, tachycardic, and mildly hypertensive. She was given a short-acting, fast-onset benzodiazepine. After 4 hours, the patient reported feeling calm and her vital signs had returned to baseline. The emergency room physician informed Mrs. J that although she had only taken a single daily dose of St. John’s wort, she had most likely experienced the side effects of an interaction between the plant extract and the SSRI. Known interactions include a manic reaction and serotonin syndrome. The patient agreed to discontinue the St. John’s wort. She was discharged and a follow-up appointment was scheduled with her psychiatrist to discuss treatment options.

Psychoactive Herbs

Many phytomedicinals (from the Greek phyto, meaning “plant”) have psychoactive properties that are used, or have been used, to treat a variety of psychiatric conditions. Adverse effects are possible, and toxic interactions with other drugs can occur with all
Clinicians should always attempt to obtain a history of herbal use during the psychiatric evaluation. Adulteration is common, and no consistent standard preparations are available for most herbs. Safety profiles and knowledge of adverse effects of most of these substances are lacking; many, if not all, of these herbs are secreted in breast milk and are contraindicated during lactation and should be avoided during pregnancy.

Many cultures have used hallucinogens, including mescaline, psilocybin, and ergots, for thousands of years to gain spiritual and personal insight. Lysergic acid diethylamide (LSD), synthesized in the 1930s, was marketed to psychiatrists and other practitioners in the late 1940s under the trade name Delysid as a tool for understanding psychosis and for facilitating psychotherapy. Using LSD reportedly helped patients capture repressed memories and deal with anxiety, and it allowed patients to gain insight through an analysis of the primary process induced by the hallucinogen. Oral doses of 150 to 250 mg were administered occasionally by psychiatrists throughout the 1950s and early 1960s to facilitate psychotherapy with some patients. In the 1960s, Timothy Leary advocated the widespread use of hallucinogens, but the drugs were outlawed as class I controlled substances in 1965.

Although no longer used for therapeutic purposes in the United States, LSD has fulfilled part of its early promise as a probe for psychosis. More recent understanding of the pharmacology of LSD and its affinity to serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT2) receptors has supported the interest in developing serotonin-dopamine antagonists (atypical antipsychotics) with the 5-HT2-receptor blocking properties. Recently, studies using methylenedioxymethamphetamine (MDMA, “ecstasy”) have been approved by the NIH to determine whether psychotherapy is facilitated when the patient is under the influence of the drug, which can affect interpersonal relationships positively by promoting feelings of empathy.

It is important not to be judgmental in dealing with patients who use phytomedicinals. They are used for various reasons: (1) as part of their cultural tradition, (2) because patients mistrust physicians or are dissatisfied with conventional medicine, or (3) because they experience relief of symptoms. If psychotropic agents are prescribed, the clinician must be extraordinarily alert to the possibility of adverse effects as a result of drug–drug interactions, because many phytomedicinals have ingredients that produce physiological changes in the body. More than 200 herbal drugs are in use; only those with psychoactive properties are listed in Table 24-5.

<tr>
<th>Name</th>
<th>Ingredients</th>
<th>Use</th>
<th>Adverse Effects</th>
<th>Interactions</th>
<th>Dosage</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Areca, areca nut, betel nut, L. Areca catechu</td>
<td>Arecoline, guvacoline</td>
<td>For alteration of consciousness to reduce pain and elevate mood</td>
<td>Parasympathomimetic overload; increased salivation, tremors, bradycardia, spasms, gastrointestinal disturbances, ulcers of the mouth</td>
<td>Avoid with parasympathomimetic drugs; atropine-like compounds reduce effect</td>
<td>Undetermined; 8–10 g is toxic dose for humans</td>
<td>Used by chewing the nut; used in the past as a chewing balm for gum disease and as a vermifuge; long-term use may result in malignant tumors of the oral cavity</td>
</tr>
<tr>
<td>Belladonna, L. Atropa belladonna, deadly nightshade</td>
<td>Atropine, scopolamine, flavonoids</td>
<td>Anxioalytic</td>
<td>Tachycardia, arrhythmias, xerostomia, mydriasis, difficulties with micturition and constipation</td>
<td>Synergistic with anti-cholinergic drugs; avoid with tricyclic anti-depressants, amantadine, and quinidine</td>
<td>0.05–0.10 mg a day; maximum single dose is 0.20 mg</td>
<td>Has a strong smell, tastes sharp and bitter, and is poisonous</td>
</tr>
<tr>
<td>Bitter orange flower, Citrus aurantium</td>
<td>Flavonoids, limonene</td>
<td>Sedative, anxiolytic, hypnotic</td>
<td>Photosensitization</td>
<td>Undetermined</td>
<td>Tincture 2–3 g per day, drug 4–6 g per day extract 1–2 g per day 1–2 g per day over 5 g can cause vomiting, headache, dizziness, cardiovascular collapse</td>
<td>Contradictory evidence; some refer to it as a gastric stimulant Estrogen-like effects questionable because root may act as estrogen-receptor blocker</td>
</tr>
<tr>
<td>Black cohosh, L. Cimicifuga racemosa</td>
<td>Triterpenes, isoerucic acid</td>
<td>For premenstrual syndrome, menopausal symptoms, dysmenorrhea</td>
<td>Weight gain, gastrointestinal disturbances</td>
<td>Possible adverse interaction with male or female hormones</td>
<td>Clinical or experimental documentation of effects is unavailable</td>
<td></td>
</tr>
<tr>
<td>Black haw, cramp bark, L. Viburnum prunifolium</td>
<td>Scopoletin, flavonoids, caffeic acids, triterpenes</td>
<td>Sedative, antispasmodic action on uterus; for dysmenorrhea</td>
<td>Undetermined</td>
<td>Anticoagulant-enhanced effects</td>
<td>1–3 g per day</td>
<td></td>
</tr>
<tr>
<td>California poppy, L. Eschscholtzia californica</td>
<td>Isoquinoline alkaloids, cyanogenic glycosides</td>
<td>Sedative, hypnotic, anxiolytic; for depression</td>
<td>Lethargy</td>
<td>Combination of California poppy, valerian, St. John’s wort, and passion flowers can result in agitation</td>
<td>2 g per day</td>
<td></td>
</tr>
<tr>
<td>Catnip, L. Nepeta cataria</td>
<td>Valeric acid</td>
<td>Sedative, antispasmodic; for migraine</td>
<td>Headache, malaise, nausea, hallucinogenic effects</td>
<td>Undetermined</td>
<td>Delirium produced in children</td>
<td></td>
</tr>
<tr>
<td>Chamomile, L. Matricaria chamomilla</td>
<td>Flavonoids</td>
<td>Sedative, anxiolytic</td>
<td>Allergic reaction</td>
<td>Undetermined</td>
<td>May be GABAergic</td>
<td></td>
</tr>
<tr>
<td>Corydalis, L. Corydalis cava</td>
<td>Isoquinoline alkaloids</td>
<td>Sedative, antidepressant; for mild depression</td>
<td>Hallucination, lethargy</td>
<td>Undetermined</td>
<td>Clonic spasms and muscular tremor with overdose</td>
<td></td>
</tr>
<tr>
<td>Cyclamen, L. Cyclamen europaeum</td>
<td>Triterpene</td>
<td>Anxiolytic; for menstrual complaints</td>
<td>Small doses (e.g., 300 mg) can lead to nausea, vomiting, and diarrhea</td>
<td>Undetermined</td>
<td>High doses can lead to respiratory collapse</td>
<td></td>
</tr>

<tr>
<td>Echinacea, <em>E. purpurea</em></td>
<td>Flavonoids, polysaccharides, caffeic acid derivatives, alkaloids</td>
<td>Stimulates immune system; for lethargy, malaise, respiratory and lower urinary tract infections</td>
<td>Allergic reaction, fever, nausea, vomiting</td>
<td>Undetermined 1-3 g per day Use in HIV and AIDS patients is controversial; potential for immunosuppression with long-term use. NCCAM studied.</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Ephedra, ma-huang</td>
<td>Ephedrine, pseudoephedrine</td>
<td>Stimulant; for lethargy, malaise, diseases of respiratory tract</td>
<td>Symptomatic relief overdose; arrhythmias, increased blood pressure, headache, irritability, nausea, vomiting</td>
<td>Synergistic with sympathomimetics, serotoninergic agents; avoid with MAOIs 1-2 g per day Administer for short periods as tachyphylaxis and dependence can occur; risk of myocardial ischemia and stroke. Banned in US diet supplement. Studies indicate improved cognition in Alzheimer’s patients after 4-5 weeks of use, possibly because of increased blood flow</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Ginkgo, <em>Ginkgo biloba</em></td>
<td>Flavonoids, ginkgolides A, B</td>
<td>Symptomatic relief of delirium, dementia; improves concentration and memory deficits; possible antidote to SSRI-induced sexual dysfunction</td>
<td>Allergic skin reactions, gastrointestinal upset, muscle spasms, headache</td>
<td>Anticoagulant; use with caution because of its inhibitory effect on PAF; increased bleeding possible 120-240 mg per day Several varieties exist: Korean (most highly valued), Chinese, Japanese, American (Panax quinquefolius)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Ginseng, <em>Panax ginseng</em></td>
<td>Triterpenes, ginsenosides</td>
<td>Stimulant; for fatigue, elevation of mood, immune system</td>
<td>Insomnia, hypertension, and edema (called ginseng abuse syndrome)</td>
<td>Not to be used with sedatives, hypnotic agents, MAOIs, antidiabetic agents, or steroids; has anticoagulant action (discontinue 7 days before surgery) 1-2 g per day Several varieties exist: Korean (most highly valued), Chinese, Japanese, American (Panax quinquefolius)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Heather, <em>Calluna vulgaris</em></td>
<td>Flavonoids, catechin, triterpenes, β-sitosterol</td>
<td>Anxiolytic, hypnotic</td>
<td>Undetermined</td>
<td>Undetermined Efficacy for claimed uses is not documented</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Hops, <em>Humulus lupulus</em></td>
<td>Humulone, lupulone, flavonoids</td>
<td>Sedative, anxiolytic, hypnotic; for mood disturbances, restlessness</td>
<td>Contraindicated in patients with estrogen-dependent tumors (breast, uterine, cervical)</td>
<td>Hyperthermia effects with phenothiazine antipsychotics and with CNS depressants 0.5 g per day May decrease plasma levels of drugs metabolized by CPY450 system</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Horehound, <em>Ballota nigra</em></td>
<td>Diterpenes, tannins</td>
<td>Sedative</td>
<td>Arrhythmias, diarrhea, hypoglycemia, possible spontaneous abortions</td>
<td>May enhance serotonergic drug effects, may augment hypoglycemic effects of drugs 1-4 g per day May cause abortion</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Jambolan, <em>Syzygium cumini</em></td>
<td>Oleic acid, myristic acid, palmitic and linoleic acid, tannins</td>
<td>Anxiolytic, antidepressant</td>
<td>Undetermined</td>
<td>Undetermined In folk medicine, a single dose is 30 seeds (1.9 g) of powder</td>
<td></td>

*No reliable, consistent, or valid data exist on dosages or adverse effects of most phytomedicinals.*

*Flavonoids are common to many herbs. They are plant by-products that act as antioxidants (i.e., agents that prevent the deterioration of material such as DNA [deoxyribonucleic acid] via oxidation). AIDS, acquired immunodeficiency syndrome; CNS, central nervous system; GABA, γ-aminobutyric acid; HIV, human immunodeficiency syndrome; MAOIs, monoamine oxidase inhibitors; NIH, National Institutes of Health; PAF, platelet-activating factor; SSRIs, serotonin reuptake inhibitors; NCCAM, National Center for Complementary Medicine and Alternative Medicine.*
Homeopathic healing was developed in the early 1800s by Samuel Hahnemann, a German physician (Fig. 24-4). It is based on the concept that self-healing is a basic characteristic of human life and that special medications can aid this inherent process. The homeopathic pharmacopoeia is unique in several ways. First, it contains more than 2,000 medications, including those from plants, such asaconite, ergot, and hellebore; minerals, such as silver, copper, gold, and iodine; and animals, such as snake and jellyfish venom and tissue extracts. Second, medications are prepared as tinctures (i.e., mixed with 95 percent grain alcohol) or as pills with lactose fillers. Finally, medications are dispersed in infinitesimally dilute solutions, such as 1 to 1,020,000, which prevents the medication from being detected by conventional chemical methods. Homeopaths claim that the therapeutic effect is based on “molecular medicine.”

**FIGURE 24-4** Samuel Hahnemann (1755–1843). (From the New York Academy of Medicine, New York, NY, with permission.)

Hahnemann based his drug treatment on the following assumptions: medical substances elicit a standard array of signs and symptoms in healthy people, and the medicine whose effect in normal persons most closely resembles the illness being treated is the one most likely to initiate a curative response. Thus, a medication that produces nausea would be used to treat nausea, except that it would be given in dilute amounts. This law of similars—*Similia similibus curantur* (“Let like be cured by like”)—led to coining of the word homeopathy (“similar experiences”). In traditional medicine, such highly dilute substances are considered to have no effect, and no pharmacological research studies demonstrate otherwise.

Homeopathic medical schools are no longer found in the United States (the last one was Hahnemann University Medical School, which closed in 1994); nevertheless, the practice of homeopathy is increasing in the United States and around the world. In Europe, homeopathy is extraordinarily popular. Homeopathic medicines are sold over the counter in the United States. Homeopathic remedies sold in the United States must meet the standards of monographs in the Homeopathic Pharmacopoeia of the United States (HPUS), which was recognized in the Food, Drug and Cosmetic Act with authority equivalent to that of the United States Pharmacopeia (USP). To date, no NCCAM studies have been done on homeopathic
LIGHT AND MELATONIN THERAPY
Light therapy is based on the concept that humans are subject to circadian rhythms (from the Latin words *circa* [“around”] and *dies* [“day”]) that affect physiological processes in predictable ways. There are 24-hour cycles of rest and activity that include changing levels of corticosteroids, electrolyte excretion, and physiological processes; for instance, blood pressure is higher during the day than at night. By varying light exposure, circadian rhythms can be altered. The concentration of the hormone melatonin, produced by the pineal gland, is highest in the bloodstream at night and is low or absent during the daylight. Melatonin is believed to regulate sleep, and exogenous melatonin (available over the counter) produces drowsiness in normal people. Artificial bright-light therapy (over 2,500 lux) is a proven method used to treat depressive disorder with seasonal pattern, which is seen during the winter months when daylight hours are reduced.

MACROBIOTICS
Macrobiotics (from the Greek words *makros* [“long”] and *bios* [“life”]) is a health practice that focuses on living in harmony with nature, using mainly a balanced diet. Macrobiotics became associated with the biblical patriarchs, the Chinese sages, and the Ethiopians of Africa, who were said to live 120 years or more. In 1797, a German physician and philosopher, Christoph W. Hufeland wrote an influential book on diet and health, *Macrobiotics or the Art of Prolonging Life*.

Macrobiotic foods are classified as *yin* (cold and wet) and *yang* (hot and dry); the goal is to keep *yin* and *yang* in balance. The diet consists of 50 percent grain products, 25 percent cooked or raw vegetables, 10 percent protein, 10 percent vegetable or fish soup, and 5 percent teas and fruits. Prolonged use of the diet can result in vitamin and mineral deficiencies.

MASSAGE
Massage is a treatment that involves manipulation of the soft tissues and the surfaces of the body. It was prescribed for the treatment of diseases more than 5,000 years ago by Chinese physicians, and Hippocrates considered it to be a method of maintaining health.

Massage is believed to affect the body in several ways: it increases blood circulation, improves the flow of lymph through the lymphatic vessels, improves the tone of the musculoskeletal system, and has a tranquilizing effect on the mind. Massage techniques have been described in various ways: stroking, kneading, pinching, rubbing, knuckling, tapping, or applying friction. Massage is most often done with the hands and fingers, but vibrating machines and electrical stimulation are also used. The different types of massage therapies that have evolved over the years are more similar than different. These include Swedish, Oriental, Shiatsu, and Esalen massages. Studies have proved massage useful to reduce anxiety and pain perception. Most persons who experience massage find it physically and mentally restorative. NCCAM studies have shown massage to be of benefit in the treatment of pain, especially pain related to joint disease.
Meditation is a technique that involves entering a trance state by focusing thought on a word or sound (a mantra), an object (e.g., a burning candle), or a movement (e.g., an oscillating disk). During the trance, the person experiences a state of calm. A meditative trance has physiological effects, all associated with decreased anxiety: heart and respiratory rates slow, blood pressure decreases, and alpha brain waves increase.

Transcendental meditation (TM), developed by the Indian mystic Maharishi Mahesh Yogi, was introduced into the United States in the 1950s. TM uses mantras based on personal characteristics to induce a trance state. In the 1960s, a physician, Herbert Benson, developed the relaxation response, which used mantras and breath control as a treatment for stress and stress-related disorders.

Mindfulness Meditation

Mindfulness meditation is derived from Buddhist practices of meditation and refers to paying attention to the present and being aware of the present using all sensory modalities. As thoughts flow through the mind during meditation, they are viewed nonjudgmentally, accepted for what they are, reflective of our “true nature.” It is a process of self-exploration and self-inquiry. NCCAM studies have shown changes in brain, particularly left side anterior activation during meditation also associated with significant improvement in subjective and objective symptoms of anxiety and panic. One study reported improvement in women with irritable bowel syndrome.

Mindfulness Therapy

The concept of mindfulness and has been translated into a type of psychotherapy in which therapist and patient focus are on the here and now rather than past events. Patients are encouraged to become aware of how they are feeling and what they are thinking in the moment. As they examine their experienced emotion about current events or conflicts, insights leading to change in behavior or attitudes occur.

Moxibustion

Moxibustion is based on theories of Oriental medicine in which energy forces are balanced by applying heat to stimulate specific acupoints. The heat is generated by burning dry mugwort leaves (Artemisia vulgaris, known as moxa). Heat is applied either directly or indirectly. In the direct method, dried moxa is rolled into small cones and placed on the skin. The tops of the cones are lit, but they are extinguished as soon as heat is felt. In the indirect method, a burning cigar-like moxa is held near the skin at acupoints.

Moxibustion is used in musculoskeletal disorder, arthritis, asthma, and eczema. As with many other alternative therapies, however, no scientific clinical trials are available to show its effectiveness.

Naturopathy
Naturopathy is a health care system intended to ensure a healthy mind and body based on maintaining healthy nutrition, pollution-free air and water supplies, and exercising regularly. The treatment is based on the belief that the body has the power to heal itself; it requires the patient’s active participation in the health maintenance program.

Naturopathy developed in Germany in the later 19th century under the guidance of Benedict Lust, who prescribed hydrotherapy (alternating hot and cold water) as a form of natural healing. Lust came to the United States, became an osteopathic physician, and founded the American School of Naturopathy in 1902. Since then, naturopathic medicine has grown into a major form of health care, which uses an eclectic group of methods in addition to hydrotherapy. These methods include eating specialized diets, homeopathy, breathing ionized air, using fomentations (the application of hot and cold compresses), taking colonic irrigations and enemas, drinking pollution-free water, eating foods grown organically, and using massage therapy, herbs, and rest therapy. Naturopathic physicians are licensed in several states (Alaska, Connecticut, New Hampshire, among others), but because no standard regulation of the field exists, persons with minimal or no educational background set up practices.

ORIENTAL MEDICINE

Oriental medicine is a broad term covering the traditional medicines of China, Korea, Japan, Vietnam, Tibet, and other Asian countries. In general, the techniques of Oriental medicine were first developed in China and include acupuncture, moxibustion, herbology, massage, cupping, gwa sha (scraping away toxins), breath work, qi gong (see below), and exercise (tai chi). Chinese medicine is a coherent and independent system of thought and practice based on ancient texts. It is the result of a continuous process of critical thinking, extensive clinical observation, and testing, and it represents a thorough exposition of material by respected clinicians and theoreticians. It is rooted in philosophy, logic, sensibility, and habits of civilization foreign to Western civilization and, therefore, is difficult for Western physicians to understand. The basic theory is that a life force, called chi energy, flows in us in a harmonious, balanced way. This harmony and balance signify health. When the life force does not flow properly, disharmony and imbalance, or illness, result.

OSTEOPATHIC MEDICINE

The scope of osteopathic medicine is similar to allopathic medicine and is best indicated by the fact that doctors of osteopathy (DO) are licensed to practice in every state and are accepted into medical, surgical, and psychiatric residency programs and the military on the same basis as medical doctors (MD); they are qualified to practice in every branch of clinical medicine and take the same licensure examinations as MDs. Their medical education is identical to that of MDs, except that they have additional training in disorders of the musculoskeletal system, in which DOs consider themselves more knowledgeable than MDs.

As of 2012 there were 29 osteopathic medical schools in the United States. Approximately 82,000 osteopaths treat about 30 million patients each year. Osteopathy was developed by Andrew Taylor Still, M.D. (1828–1917), who founded the
American School of Osteopathy in Kirksville, Missouri (now Kirksville College of Osteopathic Medicine), in 1892. Disease is viewed in the same way as in allopathic medicine; however, special emphasis is placed on proper musculoskeletal alignment as a prerequisite for health maintenance. Osteopaths may rely on the manipulation of body parts, particularly the craniosacral spinal axis, as part of a treatment plan. Osteopathic manipulation therapy is perceived as an adjunct, not a substitute, to traditional medical, surgical, and pharmacological intervention.

**OZONE THERAPY**

Ozone, which acts as an antioxidant and disinfectant, is used conventionally for water purification, odor control, and air purification. Ozone therapy is based on the assumption that most illness is caused by viral and bacterial infection; ozone is used to treat medical conditions that range from influenza to cancer and acquired immunodeficiency syndrome (AIDS). The first ozone generators were developed by Werner von Siemens in Germany in 1857, and ozone was used therapeutically to purify blood shortly thereafter in Germany and other European countries.

Ozone therapy introduces ozone into the body in various ways. These include drinking ozonated water; ozone limb bagging, in which ozone is pumped into an airtight bag that covers an arm or leg; breathing ozone bubbled through olive oil or topically applying ozonated olive oil; insufflations, in which a catheter is inserted into the rectum or vagina with ozone administered at a slow flow rate; and autohemotherapy, in which a person’s own ozonized blood is reintroduced into the body.

**PAST LIFE MEDICINE**

In past life medicine, the healing process is aided by contact with spiritual beings that are believed to have the ability to reverse illness and maintain health. The spirits are approached through the use of altered states of consciousness, so-called *channeling*, higher states of awareness, and transmissions from spiritually evolved beings. Past life regression using hypnosis allows a person to experience past life events (via imagery).

A 40-year-old man, in good health, with an obsessive fear of death was referred to an integrative psychiatrist to deal with his preoccupations about dying. The patient was placed in a trance state under hypnosis and asked to imagine and describe a past life. He described himself as an itinerant silk merchant living in 16th-century France. He was married, had eight children, and was content with his life. He was asked to describe his death and proceeded to do so. He was 90 years old when he died, surrounded by his family who were at his bedside. He knew he was dying and described the process as a “peaceful falling away.” Following the session, his fears about dying diminished; when he became anxious about death, he remembered the past life narrative and was able to relax.

**PRAYER**
The pervasive interest in faith healing, the curative anecdotes of television evangelists, and the millions of hopeful individuals visiting religious shrines in search of relief give witness to the continuing interest in, and prevalence of, prayer and spirituality in the process of healing. Some religious groups specifically recommend against standard psychiatric therapies and offer their own approach as the only valid alternative for mental and spiritual health. Others view prayer as a form of distant healing defined by the psychic Elizabeth Targ as any purely mental effort undertaken by one person with the intention of improving the physical or emotional well-being of another.

Some advocate the use of shared prayer, silent prayer, and distant or “intercessory” prayer (praying on behalf of someone else for a specific purpose) to benefit patients. Studies to date are inconclusive, however, on the impact of prayer on medical outcomes. Surveys indicate that 92 percent of a sample of inner-city homeless women reported one or more spiritual or religious practices. Some 48 percent reported that prayer was significantly related to less use of alcohol or street drugs or both and fewer perceived worries and depression. Recent epidemiological research indicates that religious beliefs and practices are negatively correlated with substance abuse and positively correlated with health status. Also 12-step programs have a long history of successfully incorporating prayer and spirituality in the treatment of addictive behavior. Personal belief in religion and active attendance at worship has been correlated with a moderately decreased incidence of depression and hypertension.

**QI GONG**

Chinese *qi gong* has been practiced for more than 2,000 years. Translated directly, *qi gong* means the skill or work (*gong*) of cultivating energy (*qi*). It is a Chinese exercise system that attracts and directs the vital life energy (see “Oriental Medicine” above), enabling practitioners to build up their health, prevent illness, and increase vitality. “Still” *qi gong* is practiced as a motionless meditation with the emphasis on breath and intentional thoughts. “Moving” *qi gong* involves external movements under the conscious direction of the mind. Electroencephalogram studies have detected measurable differences in the brain patterns of practitioners. Purported benefits include increased autoimmune cell production, reduced hypertension, and decreased incidence of falls in the elderly.

**REFLEXOLOGY**

Reflexology is the gentle massaging of the feet, hands, and ears to stimulate the body’s natural healing power. It is used to alleviate tension by clearing crystalline deposits under the skin that may interfere with the natural flow of the body’s energy. Reflexologists believe that all body parts can be mapped out on the soles or sides of the feet; for instance, the tip of the second toe represents the eye. Applying pressure to a particular area of the foot can relieve disorders related to the represented body parts. NCCAM studies have shown some benefit from reflexology in patients with irritable bowel syndrome.

**REIKI**
Reiki is a Japanese word with the general meaning of “healing.” (Rei means “universal” or “spiritual,” and ki is “life force energy.”) It was developed by Mikao Usui in 1922 (Fig. 24-5). The two degrees of Reiki healing are as follows. First-degree Reiki practitioners use light, nonmanipulative touch to the head and torso to precipitate a flow of healing energy, called Reiki, drawn and into the patient according to the recipient’s needs. Second-degree healing enables practitioners to access this energy for distant healing when touch is impossible. Reiki treatment typically creates an almost immediate feeling of relaxation, which may reduce the biochemical effects of prolonged stress. First-degree Reiki is easily learned and is a method that patients use to decrease stress, anxiety, insomnia, and pain. Reiki is also used in hospices for pain management, to support a peaceful death, and to provide emotional support for family members. It is also beneficial in cardiovascular disease as a means to lower blood pressure and reduce cardiac arrhythmias. The mechanism of action is unknown, however, the autonomic nervous system is involved, especially parasympathetic impulses.

FIGURE 24-5 Mikao Usui (1865–1926), a Japanese philosopher who was the founder of Reiki healing.

ROLFING

Rolfing is a type of massage that was developed by an American biochemist, Ida Rolf (1896–1979), to relieve tension in muscle, connective tissue, and fascia, which she believed caused musculoskeletal diseases, such as arthritis and fibromyalgia. Therapy consists of deep, sometimes painful, massage to produce flexible planes between muscle groups throughout the body. Rolf discovered that she could achieve remarkable changes
in posture and structure by manipulating the body’s myofascial system; as various parts of the body are massaged, past memories and emotional states are often released. In this sense, Rolfing is a psychophysiological experience. No NCCAM studies on Rolfing have been performed.

**SHAMANISM**

A shaman (Fig. 24-6) is an individual who is believed to have the power to heal the sick and communicate with the spirit world. Individuals having this designation can be found in many parts of the world, including American aboriginal groups (Native Americans and Alaskan natives). Qualifications of a medicine man (or woman) are determined by a series of initiatory trials and teaching and “certification” by qualified, recognized elders. Shamanistic practices often include cleansing ceremonies, such as fasting or sweating, and so-called vision quests, which are accompanied by hallucinations. The ceremony is sometimes facilitated by rhythmic sounds, dancing, physical pain or privation, and the use of “spiritual herbs.” Through this process, the shaman escorts the soul of the dying to the afterlife. Shamanistic practices are also used to provide solutions to insolvable personal or social problems.
SNOEZELLEN

This is a term for a system of multisensory stimulation (e.g., lighting effects, tactile surfaces, meditative music, and smell of essential oils) generally conducted in special rooms for 30 to 60 minutes per session. Snoezelen originated in the Netherlands in the field of learning disability and autism with children but has been adapted for use in dementia. Snoezelen may also improve behavioral disturbances such as apathy, mood, and restless or repetitive behaviors. One study showed Snoezelen to be comparable to “reminiscence therapy” (e.g., using newspapers of nostalgic items to allow a person to talk about old memories) for acute agitation in dementia. Lack of widespread availability and potentially high costs for maintaining the therapy may limit its applicability.

SOUND AND MUSIC THERAPY

Sound therapy is an ancient technique in which sounds (e.g., chants, bell rings, or drum beats) are used to create vibrations in the body and believed to have healing powers. Practitioners claim that a sense of relaxation can also be achieved. Sound therapy is used in Ayurveda to promote health, with claims of reducing tumor growth by using certain sounds known as *Sama Veda*. Music therapy uses the sound of musical instruments, such as the flute, to achieve similar results. In the Bible, David attempted to treat King Saul’s depression by playing the harp. The effect of music and sound on psychophysiological processes is under investigation at various academic centers.

TAI CHI

*Tai chi*, or *tai chi chuan*, is one of the most popular Asian movement arts used in the West. This ancient Chinese technique is designed to increase the life force in the body through a series of slow circular movements. It is a moving form of meditation and is based, as are other Chinese methods, on the search for perfect balance between *yin* and *yang* energies.

The practitioner performs sequences of movements that last from 5 to 30 minutes. A session may last a couple of hours and is typically performed in early morning. The practitioner is expected to focus on breathing and its precise synchronization with the movements. *Tai chi chuan* is believed to help mainly stress-related problems and conditions and so is primarily used to treat anxiety, depression, muscular tension, high blood pressure, and other cardiovascular conditions. NCCAM studies have shown improvement in exercise tolerance in patients with cardiovascular disease who practice *tai chi*.

THERAPEUTIC TOUCH

Therapeutic touch is the technique of healing with hands. It was developed by a nurse, Dolores Krieger, in the 1970s. Energy is believed to be transferred by laying the hands
Therapeutic touch has gained popularity in the nursing profession, as well as among some physicians. NCCAM studies have shown therapeutic touch to be of value in patients with chronic neck pain.

**TIBETAN MEDICINE**

The Tibetan health system dates to about the 7th century A.D. The Tibetan king Songsten Gampo is credited with its creation from the synthesis of various, more ancient sources. It has elements of Arabic, Indian, and Chinese health systems. In Tibet, its practice is closely related to religion and magic. Disease is believed to be the result of imbalance between the three components or humors of the living organism: wind (breathing and movement in general), bile (related to digestion and temperament), and phlegm (related to sleep, joint mobility, and skin elasticity). Imbalance can be caused by ignorance of health principles, environmental assaults, or improper diet. Treatment consists of restoring the balance between the different humors through the use of herbal medicine and accessory therapies, such as massage, moxibustion, acupuncture, appropriate diet, religious rituals, and purification techniques.

**TRAGER METHOD**

The Trager method, developed by Milton Trager, a Chicago physician, is a technique of movement reduction to aid individuals suffering from polio and other neuromuscular disorders. The client, typically in 60- to 90-minute sessions, is instructed to relax all conscious muscles and to allow the unconscious to choose natural, less restrictive body movements, as guided by the practitioner. This method is particularly suitable to individuals with back pain and severely restricted movement.

**YOGA**

Yoga (“yoking” or “union” in Sanskrit) is a comprehensive philosophical system with the goal of preparing an individual to unite with the supreme being. The technique of early yoga seeks to bring into balance all the disparate aspects of body, mind, and personality. Early evidence of yoga practice dates back to 5,000 years ago in India, and it has been practiced as a religion and health system ever since. The West grew familiar with yoga through the practice of Hatha Yoga and an emphasis on the physical collection of *asanas* (postures). The other aspects of the system, *pranayama* (breathing exercises) and *dhyana* (meditation), and other forms of yoga are gaining adoption.

Recent studies in people with chronic low-back pain suggest that yoga poses may help reduce pain and improve function. Other health benefits such as reducing heart rate and blood pressure and reducing anxiety and depression have been reported.

According to the 2007 National Health Interview Survey (NHIS), yoga is the sixth most commonly used complementary health practice among adults. More than 13 million adults practice yoga. There are many training programs for yoga teachers throughout the country. These programs range from a few days to more than 2 years. Standards for teacher
INTEGRATIVE PSYCHIATRY

A new type of psychiatry, called *integrative psychiatry*, selectively incorporates elements of complementary and alternative medicine into practice methods. It emphasizes treatment rather than diagnosis and views the patient holistically, taking into account not only mind–body issues and interactions but spiritual values as well. Integrative psychiatry is also concerned with prevention of illness, emphasized by having the patient pay attention to lifestyle factors such as diet and exercise. Stress reduction involves use of yoga, meditation, or other relaxation exercises. Attention is paid to stress factors related to work and interpersonal relationships.

History

At one time, hypnosis and biofeedback were considered alternative therapies out of the mainstream of traditional psychiatric practice. These modalities are now incorporated into standard psychiatric practice. Hypnosis, for example, is used by psychiatrists for a variety of disorders, and dynamically oriented psychiatrists use hypnotherapy in their work to enable a patient to recover feelings and memories that are repressed and not otherwise available for analysis. In the middle of the 20th century, workers such as Paul Schilder, in his book *The Image and Appearance of the Human Body*, described how one’s physiology and physiognomy could be influenced by psychological experiences during various developmental stages. More recently, mainstream psychiatrists, such as Brian Weiss, have described their use of past life regression as a therapeutic method and a means of accessing unconscious material.

Methods

Any of the complementary methods described in this section can be integrated into standard psychotherapeutic practice, although some lend themselves better than others. For example, during a Reiki treatment, a patient tends to be in a relaxed state and may have feeling tones, images, or thoughts that would not ordinarily be discussed. In an integrative therapy session, those mental and physical phenomena would be verbalized and subject to analysis and interpretation. Similarly, a patient having past life regression may have an elaborate narrative about his or her past life that would be carefully examined by the integrative psychiatrist for its relevance to current life experiences. Most integrative psychiatrists view past-life narratives as dynamic representations of the patient’s unconscious wishes and fears; some view them as representations of actual past lives. In either case, the material is used to help patients gain greater insight and understanding of themselves in their current life.

Complementary and alternative techniques that involve body manipulation (e.g., craniosacral manipulation, massage, or the Alexander technique) lend themselves to integrative psychiatric therapy. As mentioned, the image persons have of their body and the way in which the body is held (e.g., stooped posture) are heavily influenced both by genetics and by life experiences. Depressive facies, Veraguth’s folds, and other physiologic correlates of mood have long been recognized in the psychiatric literature. The integrative psychiatrist uses this and other bodily markers as a way to gain access to previously
unrecognized neurotic conflict. Patients with somatic symptom disorders or dysmorphophobia are often helped by such approaches, as are patients with eating disorders who have major body image distortions.

Any technique that involves manipulation of a body part can potentially elicit an image, thought, or feeling related to the experience. A patient experiencing a back rub may have myriad associations to the experience that are examined in the session. Some patients cannot tolerate being touched, a trait that is almost always related to some past traumatic experience. Body manipulation can be geared to correcting abnormalities. In the Alexander technique, careful attention is paid to posture and body alignment. As the corrective procedures unfold, patients may gain understanding and insight into what caused the defective or inefficient postural attitude in the first place.

Finally, spiritual beliefs derived from Judeo-Christian, Native American, and Eastern religious thought can be integrated into traditional psychotherapy. Workers such as Alan Watts incorporated Zen Buddhism into Western psychotherapy more than 50 years ago. Psychiatrists are working with Native American healers to help patients diminish anxiety, especially regarding death and dying.

Other Issues

Ideally, the psychiatrist practicing integrative therapy should be schooled in one or more of the complementary methods he or she plans to employ. In some cases, a complementary practitioner may work in conjunction with the psychiatrist, especially if the psychiatrist is not schooled in a particular method. At times, patients may be expert in a field (e.g., yoga) and seek out the integrative psychiatrist to enlarge on their experience. Integrative psychiatrists may use psychoactive herbs and homeopathic medicinals alone or in conjunction with traditional psychopharmacologic agents, mindful of the possibility of adverse drug–drug interactions.

Ethical Issues

The same standards that apply to traditional psychiatric practice and psychotherapy apply to integrative psychiatry. Because some of the techniques involve a laying on of hands or place the patient in a more dependent and vulnerable state than traditional psychotherapy techniques, boundary issues must be carefully evaluated. Currently, no standards of practice exist for this method other than those to which physicians have always been held, including doing no harm. As in complementary and alternative medicine generally, careful outcome studies are needed if this new amalgam is to prove its worth.

References

Davidson JR, Crawford C, Ives JA, Jonas WB. Homeopathic treatments in psychiatry: A systematic review of randomized
In the fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), in a section called Other Conditions That May Be a Focus of Clinical Attention, there is a list of conditions that are not mental disorders but that have led to contact with the mental health care system. In some instances, one of these conditions will be noted during the course of a psychiatric evaluation (e.g., divorce), although no mental disorder has been found. In other instances, the diagnostic evaluation reveals no mental disorder, but a need is seen to note the primary reason for contact with the mental health care system (e.g., homelessness).

In some cases, a mental disorder may eventually be found, but the focus of attention or treatment is on a condition that is not caused by a mental disorder. For example, a patient with an anxiety disorder may receive treatment for a marital problem that is unrelated to the anxiety disorder itself.

Table 25-1 lists the many conditions that may be a focus of clinical attention or that may influence the diagnosis, treatment, or course of a mental disorder that is contained in DSM-5. The list of conditions that make up this category cover the entire life cycle from infancy through childhood, adolescence, adulthood, and old age. The list of conditions covers almost every conceivable life circumstance from divorce to problems related to being in military service. In one sense, they represent the vicissitudes of life or, as Shakespeare has Hamlet state, “the slings and arrows of outrageous fortune.” Each of these conditions or circumstances is capable of having a profound input on a particular mental illness or on the human experience in general.

### Table 25-1

**Conditions That May Be a Focus of Clinical Attention**
The conditions discussed in this chapter include the following: (1) malingering, (2) bereavement, (3) occupational problems, (4) adult antisocial behavior, (5) religious or spiritual problem, (6) acculturation problem, (7) phase of life problem, (8) noncompliance with treatment for a mental disorder, and (9) relational problems. Problems related to the maltreatment and abuse of children is covered in Section 31.19c, and problems related to the physical and sexual abuse of adults is covered in Chapter 26.

**MALINGERING**

Malingering is the deliberate falsification of physical or psychological symptoms in an attempt to achieve a secondary gain such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs. Under some circumstances, malingering may represent adaptive behavior—for example, as mentioned below, feigning illness while a captive of the enemy during wartime.
Malingering should be strongly suspected if any combination of the following is noted: (1) medicolegal context of presentation (e.g., the person is referred by an attorney to the clinician for examination or is incarcerated), (2) evident discrepancy between the individual’s claimed stress or disability and the objective findings, (3) lack of cooperation during the diagnostic evaluation and in complying with the prescribed treatment regimen, and (4) the presence of antisocial personality disorder.

Epidemiology
A 1 percent prevalence of malingering has been estimated among mental health patients in civilian clinical practice, with the estimate rising to 5 percent in the military. In a litigious context, during interviews of criminal defendants, the estimated prevalence of malingering is much higher—between 10 and 20 percent. Approximately 50 percent of children presenting with conduct disorders are described as having serious lying-related issues.

Although no familial or genetic patterns have been reported and no clear sex bias or age at onset has been delineated, malingering does appear to be highly prevalent in certain military, prison, and litigious populations and, in Western society, in men from youth through middle age. Associated disorders include conduct disorder and anxiety disorders in children and antisocial, borderline, and narcissistic personality disorders in adults.

Etiology
Although no biological factors have been found to be causally related to malingering, its frequent association with antisocial personality disorder raises the possibility that hypoarousability may be an underlying metabolic factor. Still, no predisposing genetic, neurophysiological, neurochemical, or neuroendocrinological forces are presently known.

Diagnosis and Clinical Features
Avoidance of Criminal Responsibility, Trial, and Punishment. Criminals may pretend to be incompetent to avoid standing trial; they may feign insanity at the time of perpetration of the crime, malinger symptoms to receive a less harsh penalty, or attempt to act too incapacitated (incompetent) to be executed.

Avoidance of Military Service or of Particularly Hazardous Duties. Persons may malinger to avoid conscription into the armed forces and, after being conscripted, they may feign illness to escape from particularly onerous or hazardous duties.

Financial Gain. Modern malingers may seek financial gain in the form of undeserved disability insurance, veterans’ benefits, workers’ compensation, or tort
Avoidance of Work, Social Responsibility, and Social Consequences. Individuals may malinger to escape from unpleasant vocational or social circumstances or to avoid the social and litigation-related consequences of vocational or social improprieties.

An owner of a previously successful photographic equipment supplier declared bankruptcy in a way that the government maintained was illegal. Subsequently, the government indicted the defendant on various counts of fraud. The defendant’s counsel maintained that the defendant was too depressed to cooperate with him and that, because of that depression, he experienced memory loss that made it impossible to understand what had occurred and therefore impossible to provide a meaningful defense. The government’s forensic psychiatrist evaluated the defendant to ascertain the nature of his depression and to determine whether it was causing cognitive problems.

When asked early in his evaluation when his birthday was, he responded, “Oh, what does it matter? It was in the 40s or 50s.” Similarly, when queried about where he was born, he said, “Some place in Hungary.” Even when pressed for more specifics, he refused to elaborate. Yet, at many points later in his evaluation, he responded with complete, often detailed, information about transactions not related to those for which he had been indicted. It was the impression of the evaluator that the defendant was malingering in a gross and inconsistent fashion, incompatible with the kinds of decreases in cognitive skills that occasionally attend major depression. (Adapted from case of Mark J. Mills, J.D., M.D., and Mark S. Lipian, M.D., Ph.D.)

Facilitation of Transfer from Prison to Hospital. Prisoners may malinger (fake bad) with the goal of obtaining a transfer to a psychiatric hospital from which they may hope to escape or in which they expect to do “easier time.” The prison context may also give rise to dissimulation (faking good), however; the prospect of an indeterminate number of days on a mental health ward may prompt an inmate with true psychiatric symptoms to make every effort to conceal them.

Admission to a Hospital. In this era of deinstitutionalization and homelessness, individuals may malinger in an effort to gain admission to a psychiatric hospital. Such institutions may be seen as providing free room and board, a safe haven from the police, or refuge from rival gang members or disgruntled drug cronies who have made street life even more unbearable and hazardous than it usually is.

A robust, neatly attired man presented to the psychiatric emergency department in the early-morning hours. He stated that “the voices” were worse and that he wished to
be readmitted to the hospital. When the psychiatrist challenged him, observing that he had just been discharged that afternoon, that he routinely left the hospital in the morning and demanded rehospitalization at night, and that, despite multiple hospitalizations, his reported history of hallucinations had been increasingly doubted, the man became belligerent. When the psychiatrist still refused to admit him, the patient grabbed the psychiatrist’s clothes, threatening him but inflicting no harm. The psychiatrist asked the hospital police to escort him off the grounds. The patient was told he could seek readmission to his regular ward during the day. Subsequent contact with the patient’s ward revealed that their diagnoses were substance abuse and homelessness; his apparent schizophrenia appeared never to have been an actual issue in his treatment. (Courtesy of Mark J. Mills, J.D., M.D., and Mark S. Lipian, M.D., Ph.D.)

Drug Seeking. Malingerers may feign illness in an effort to obtain favored medications, either for personal use or, in a prison setting, as currency to barter for cigarettes, protection, or other inmate-provided favors.

The plaintiff, a woman in her late 20s, was injured while dancing at a club. Although her claim initially appeared bona fide, subsequent investigation cast doubt on the mechanism of injury that she claimed—namely, that a misplaced electrical cord under a carpet caused her to slip. This was true, she claimed, even though she had to been dancing in a particularly jerky manner that could have easily caused problems without tripping.

Subsequently, she sought medical and surgical treatment for torn cartilage in her injured knee. Even though the initial surgery went well, she kept reinjuring the knee with various “slips.” As a result, she requested narcotic analgesics. A careful medical record review revealed that she was obtaining such medications from multiple practitioners and that she had apparently forged at least one prescription.

In reviewing the case before binding arbitration, it was the opinion of the orthopedic and psychiatric consultants that, although the initial injury and reported pain were real, the plaintiff consciously elaborated her injuries to obtain the desired narcotic analgesics. (Courtesy of Mark J. Mills, J.D., M.D., and Mark S. Lipian, M.D., Ph.D.)

Child Custody. Minimizing difficulties or faking good for the sake of obtaining child custody can occur when one party accurately accuses the other of being an unfit parent because of psychological conditions. The accused party may feel compelled to minimize symptoms or to portray him- or herself in a positive light to reduce chances of being deemed unfit and losing custody.
Differential Diagnosis

Malingering must be differentiated from the actual physical or psychiatric illness suspected of being feigned. Furthermore, the possibility of partial malingering, which is an exaggeration of existing symptoms, must be entertained. Also, the possibility exists of unintentional, dynamically driven misattribution of genuine symptoms (e.g., of depression) to an incorrect environmental cause (e.g., to sexual harassment rather than to narcissistic injury).

It should also be remembered that a real psychiatric disorder and malingering are not mutually exclusive.

Factitious disorder is distinguished from malingering by motivation (sick role vs. tangible pain), whereas the somatoform disorders involve no conscious volition. In conversion disorder, as in malingering, objective signs cannot account for subjective experience, and differentiation between the two disorders can be difficult. Table 25-2 lists some variables that may aid in distinguishing between these two conditions.

</table>

Course and Prognosis

Malingering persists as long as the malingerer believes it will likely produce the desired rewards. In the absence of concurrent diagnoses, after the rewards have been attained, the feigned symptoms disappear. In some structured settings, such as the military or prison units, ignoring the malingered behavior may result in its disappearance, particularly if an expectation of continued productive performance, despite complaints, is made clear. In children, malingering is most likely associated with a predisposing anxiety or conduct disorder; proper attention to this developing problem may alleviate the child's propensity to malinger.

Treatment

The appropriate stance for the psychiatrist is clinical neutrality. If malingering is suspected, a careful differential investigation should ensue. If, at the conclusion of the
diagnostic evaluation, malingering seems most likely, the patient should be tactfully but firmly confronted with the apparent outcome. The reasons underlying the ruse need to be elicited, however, and alternative pathways to the desired outcome explored. Coexisting psychiatric disorders should be thoroughly assessed. Only if the patient is utterly unwilling to interact with the physician under any terms other than manipulation should the therapeutic (or evaluative) interaction be abandoned.

**BEREAVEMENT**

Normal bereavement begins immediately after or within a few months of the loss of a loved one. Typical signs and symptoms include feelings of sadness, preoccupation with thoughts about the deceased, tearfulness, irritability, insomnia, and difficulties concentrating and carrying out daily activities. On the basis of the cultural group, bereavement is limited to a varying time, usually 6 months, but it can be longer. Normal bereavement, however, can lead to a full depressive disorder that requires treatment. Some grieving individuals present with symptoms characteristic of a major depressive episode such as depressed mood, insomnia, anorexia, and weight loss. The duration of grief and bereavement vary considerably among different cultural groups and with the same cultural group. The diagnosis of depressive disorder is generally not given unless the symptoms are still present 2 months after the loss. However, the presence of certain symptoms that are not characteristic of a “normal” grief reaction may be helpful in differentiating bereavement from depression. These include (1) guilt about things other than actions taken or not taken by the survivor at the time of the death, (2) thoughts of death other than the survivor feeling that he or she would be better off dead or should have died with the deceased person, (3) morbid preoccupation with worthlessness, (4) marked psychomotor retardation, (5) prolonged and marked functional impairment, and (6) hallucinatory experiences other than thinking that he or she hears the voice of or transiently sees the image of the deceased person.

**OCCUPATIONAL PROBLEMS**

Occupational problems often arise during stressful changes in work, namely, at initial entry into the workforce or when making job changes within the same organization to a higher position because of good performance or to a parallel position because of corporate need. Distress occurs particularly if these changes are not sought and no preparatory training has taken place, as well as during layoffs and at retirement, especially if retirement is mandatory and the person is unprepared for this event. Work distress can result if initially agreed-to conditions change to work overload or lack of challenge and opportunity to experience work satisfaction, if an individual feels unable to fulfill conflicting expectations or feels that work conditions prevent accomplishing assignments because of lack of legitimate power, or if an individual believes he or she works in a hierarchy with harsh and unreasonable superiors.
Work Choices and Changes

Young adults without role models or guidance from families, mentors, or others in their communities too often underestimate their lifetime potential abilities to learn a trade or earn a college or postgraduate degree. In addition, women and members of minority groups often feel less prepared to accept work challenges, fear rejection, and do not apply for jobs for which they are qualified. On the other hand, men, in fields in which they are underrepresented, often and confidently move up the career ladder faster (glass elevator). As part of initial interviews for evaluation of occupational problems, patients should be encouraged to consider their heretofore unrecognized, unadmitted talents; long-held, yet unexpressed, dreams and goals regarding work; actual successes in work and school; and motivation to risk learning what they would find satisfying.

Minorities and those in low-paying and low-skilled jobs too often have less job security. Business and institutional reorganization and consequent downsizing, factory closings, and moves affect many, often leaving these workers feeling hopeless and helpless about future employment, on welfare, angry, and depressed.

With ongoing and often sudden downsizing of corporations and businesses, men and women continue to struggle with unexpected job loss and premature retirement even when finances are not an issue. In addition, men, in particular, define themselves by their work roles, and thus experience more occupational distress from these changes. Women may adjust faster to retirement, but they often have less financial security than men do (white women earn approximately 80 cents on the dollar, and African American and Hispanic women earn even less for comparable work); women have generally been in lower status work positions, find themselves widowed more often than men, and are more likely to be caring for children, grandchildren, and elderly relatives. Women represent more of the single working parent group and the working poor.

Stress and the Workplace

More than 30 percent of workers report that they are under stress at work. Workplace distress is implicated in at least 15 percent of occupational disability claims. Expected distress follows recognized and uncontrollable work changes—downsizing; mergers and acquisitions; work overload; and chronic physical strains, including work noise, temperature, bodily injuries, and strain from performing computer work. According to one study, the top ten most stressful jobs in 1998 were (1) president of the United States, (2) firefighter, (3) senior corporate executive, (4) race car driver, (5) taxi driver, (6) surgeon, (7) astronaut, (8) police officer, (9) football player, and (10) air traffic controller. People who work under deadlines, such as bus drivers, are subject to hypertension.

Work frustration can also arise from an individual worker’s unrecognized (and therefore unresolved) psychodynamic issues, such as working appropriately with superiors and not relating to one’s supervisor as a parent figure. Other developmental issues include unresolved problems with competition, assertiveness, envy, fear of success, and inability to communicate verbally in a constructive manner.

After the September 11, 2001, World Trade Center tragedy, a 32-year-old, married
male firefighter, who had been away on vacation that day with his wife and children, began to exhibit changed behaviors at home and at work. At home, he appeared not to listen to his two children and, instead, focused his attention on television sporting events. At work, he also appeared to be more focused on cooking the same dinners for his peers and watching television than on interacting verbally with his remaining peers and the new chief. In the course of several months, a chaplain visited the station several times and talked to the firefighters about survivor guilt and the 9/11 tragedy, and the firefighter began to return somewhat to his former healthier behaviors. (Courtesy of Leah J. Dickstein, M.D.)

Often, work conflicts reflect similar conflicts in the worker’s personal life, and referral for treatment, unless there is insight, is in order. Some studies have found that massage therapy, meditation, and yoga at intervals during the work day relieve stress when used on a regular basis. Approaches using cognitive therapy have also helped people reduce work pressure.

Suicide Risk

Some occupations—health professionals, financial service workers, and police, the first and latter groups because of easier access to lethal drugs and weapons—both attract persons with a high suicide risk and involve increased chronic distress that may lead to higher suicide rates.

Career and Job Problems of Women

Most women work outside the home out of necessity to support themselves or their dependents (whether children or adults) or as part of a working couple. With the divorce rate remaining at the 50 percent level, many women find themselves economically poorer after a divorce than when married, although divorced men usually find their economic status improved. Despite more than four decades of increasing knowledge about and concern for women’s status in the workplace, unique gender issues, bias, and lack of accommodation to their unique needs at certain life stages (i.e., pregnancy and postpartum, major responsibility for young healthy and ill children) continue. Yet, women were the largest group establishing new small businesses in the 1990s. Many have left large corporations where they were not valued for their efforts because of their gender. Women experience problems when they are the sole woman in a man’s field. Despite increasing recognition of the need for men in relationships with women to assume home and family responsibilities, fewer than 25 percent of men do so equitably.

Women of childbearing and child-rearing ages continue to find themselves in conflict with job expectations, opportunities, and personal responsibilities. High-quality, on-site, dependent-care facilities with extended hours are rare and often out of range financially. Major unresolved work issues that are unique to women at certain life stages include flextime and paid and unpaid dependent leave options. Beyond dependent care issues, women in the workforce continue to
Experience distress after chronic and repeated sexual harassment, despite its illegality and media attention. Increasingly, more women have travel responsibilities, work long hours, work shifts beyond daylight hours, and experience personal workplace violence.

Among dual-career families and partners, the woman is more likely to move when the man chooses to move for a work opportunity than vice versa. Consequently, a woman’s career is interrupted more often. Less reluctance is seen, however, to have the two members of a relationship work for the same organization than previously, albeit usually in different departments. Work distress may also stem from continuous miscommunication, especially that based on gender.

**Working Teenagers**

With unemployment increasing, many teenagers work part time while attending high school. Consequently, stress can arise because of less parent–teenager interaction and constructive parental control issues about teens’ use of earnings, time spent away from home, and consequent behaviors both in and outside the home. When both parents or a single parent, as well as the teenager, work outside the home, often on different schedules, parent–teen verbal communication must be proactive, clear, and ongoing.

**Working within the Home**

Although most women with children of all ages must work outside the home, at times they may be home full time or part time or may work at home. When their husbands or partners work full time outside the home, problems may develop from each one’s perceived expectations of the other. Women who care for children and their home exclusively may be seen by their partners as not only economically dependent and inferior but also not as competent and not understanding of the man’s stressors and needs. Ongoing respectful listening and verbal communication must be encouraged.

People in organizations are increasingly taking work home as their work expectations increase. This work-at-home experience can and does interfere with personal lives and satisfaction, which can then have further repercussions at work.

**Chronic Illness**

As general and other medical and psychiatric treatments for chronic diseases improve, employers have been increasingly concerned about accommodating patients with acquired immunodeficiency syndrome (AIDS), diabetes mellitus, and other disorders. The issue of mandatory testing for AIDS and substance abuse (alcohol and other illegal substances) continues to be of concern. Employee assistance programs offering education about general and mental health topics have proved timely and cost effective.

**Domestic Violence**

Although occurring in the home, signs and symptoms that interfere with work often trigger identification of those who experience domestic violence. Trained professionals must question all employees experiencing work distress about domestic violence and, when indicated, refer individuals for assistance, which includes safety in the workplace.
Job Loss

Regardless of the reason for job loss, most people experience distress, at least temporarily, including symptoms of normal grief, loss of self-esteem, anger, and reactive depressive and anxiety symptoms, as well as somatic symptoms and possibly the onset of or increase in substance abuse or domestic violence. Timely education, support programs, and vocational guidance should be instituted and access to treatment made available if indicated.

Vocational Rehabilitation

Rehabilitation is often necessary for those traumatized by stresses in the workplace, those who had to take a leave of absence because of medical or psychiatric reasons, and those who have been fired. Individual or group counseling enables persons to improve personal relationships, raise self-esteem, or learn new work skills. Patients with schizophrenia may benefit from sheltered workshops in which they perform work that is geared to their level of function. Some patients with schizophrenia or autism do well in tasks that are repetitive or require obsessive concern with details.

ADULT ANTISOCIAL BEHAVIOR

Characterized by activities that are illegal, immoral, or both, antisocial behavior usually begins in childhood and often persists throughout life. The term antisocial behavior somewhat confusingly applies both to persons’ actions that are not due to a mental disorder and to actions by those who never received a neuropsychiatric workup to determine the presence or absence of a mental disorder. As Dorothy Lewis noted, the term can apply to behavior by normal persons who “struggle to make a dishonest living.”

Epidemiology

Depending on the criteria and the sampling, estimates of the prevalence of adult antisocial behavior range from 5 to 15 percent of the population. Within prison populations, investigators report prevalence figures between 20 and 80 percent. Men account for more adult antisocial behavior than do women.

Etiology

Antisocial behaviors in adulthood are characteristic of a variety of persons, ranging from those with no demonstrable psychopathology to those who are severely impaired and have psychotic disorders, cognitive disorders, and retardation, among other conditions. A comprehensive neuropsychiatric assessment of antisocial adults is indicated and may reveal potentially treatable psychiatric and neurological impairments that can easily be overlooked. Only in the absence of mental disorders can patients be categorized as displaying adult antisocial behavior. Adult antisocial behavior
may be influenced by genetic and social factors.

**Genetic Factors.** Data supporting the genetic transmission of antisocial behavior are based on studies that found a 60 percent concordance rate in monozygotic twins and about a 30 percent concordance rate in dizygotic twins. Adoption studies show a high rate of antisocial behavior in the biological relatives of adoptees identified with antisocial behavior and a high incidence of antisocial behavior in the adopted-away offspring of those with antisocial behavior. The prenatal and perinatal periods of those who subsequently display antisocial behavior often are associated with low birth weight, mental retardation, and prenatal exposure to alcohol and other drugs of abuse.

**Social Factors.** Studies have shown that in neighborhoods in which families with low socioeconomic status (SES) predominate, the sons of unskilled workers are more likely to commit more offenses and more serious criminal offenses than do the sons of middle-class and skilled workers, at least during adolescence and early adulthood. These data are not as clear for women, but the findings are generally similar in studies from many countries. Areas of family training differ by SES group. Middle-SES parents use love-oriented techniques in discipline. They withdraw affection rather than impose physical punishment as is done in low-SES groups. Negative parental attitudes toward aggressive behavior, attempts to curb aggressive behavior, and the ability to communicate parental values are more characteristic of middle- and high-SES groups than of low ones. Adult antisocial behavior is associated with the use and abuse of alcohol and other substances and with the easy availability of handguns.

**Diagnosis and Clinical Features.** The diagnosis of adult antisocial behavior is one of exclusion. Substance dependence in such behavior often makes it difficult to separate the antisocial behavior related primarily to substance dependence from disordered behaviors that occurred either before substance use or during episodes unrelated to substance dependence.

During the manic phases of bipolar I disorder, certain aspects of behavior, such as wanderlust, sexual promiscuity, and financial difficulties, can be similar to adult antisocial behavior. Patients with schizophrenia may have episodes of adult antisocial behavior, but the symptom picture is usually clear, especially regarding thought disorder, delusions, and hallucinations on the mental status examination.

Neurological conditions can be associated with adult antisocial behavior, and electroencephalograms (EEGs), computed tomography (CT) scans, magnetic resonance imaging (MRI), and complete neurological examinations are indicated. Temporal lobe epilepsy should be considered in the differential diagnosis. When a clear-cut diagnosis of temporal lobe epilepsy or encephalitis can be made, the disorder may be considered to contribute to the adult antisocial behavior. Abnormal EEG findings are prevalent among violent offenders: An estimated 50 percent of aggressive criminals have abnormal EEG findings.

Persons with adult antisocial behavior have difficulties in work, marriage, and money
matters and conflicts with various authorities. The symptoms of adult antisocial behavior are summarized in Table 25-3. (Antisocial personality disorder is discussed in Chapter 22.)

(Data from Robins L. Deviant Children Grown Up: A Sociological and Psychiatric Study of Sociopathic Personality. Baltimore: Williams & Wilkins; 1966.)

**Treatment**

In general, therapists are pessimistic about treating adult antisocial behavior. They have little hope of changing a pattern that has been present almost continuously throughout a person’s life. Psychotherapy has not been effective, and no major breakthroughs with biological treatments, including medications, have occurred.

Therapists show more enthusiasm for the use of therapeutic communities and other forms of group treatment, although the data provide little basis for optimism. Many adult criminals who are incarcerated in institutional settings have shown some response to group therapy approaches. The history of violence, criminality, and antisocial behavior has shown that such behaviors seem to decrease after age 40 years. Recidivism in criminals, which can reach 90 percent in some studies, also decreases in middle age.

**Prevention.** Because antisocial behavior often begins during childhood, the major focus must be on delinquency prevention. Any measures that improve the physical and mental health of socioeconomically disadvantaged children and their families are likely to reduce delinquency and violent crime. Often, recurrently violent persons have sustained many insults to the central nervous system (CNS) prenatally and throughout
childhood and adolescence. Consequently, programs must be developed to educate parents about the dangers to their children of CNS injury from maltreatment, including the effects of psychoactive substances on the brains of growing fetuses. Public education about the releasing effect of alcohol on violent behaviors (as well as its contribution to vehicular homicide) may also reduce crime.

In a Surgeon General’s Report on Violence and Public Health, the Committee on the Prevention of Assault and Homicide emphasized the importance of discouraging corporal punishment in the home, forbidding it in the schools, and even abolishing capital punishment by the state, saying that all are models and sanctions for violence. Since that time, capital punishment has been instituted in states that did not have it, such as New York. No evidence indicates that capital punishment reduces crime in states that have it. Opponents of capital punishment see it as “vengeance,” not punishment.

Although persons disagree about the contribution of violence in the media to violent crime, the propaganda potential of the media is universally recognized. The extent to which the media, such as television, can be used to transmit positive social values has not yet been realized. The guidelines issued by the television industry to indicate the amount of sex and violence in programs is an attempt to deal with the issue; however, program content that espouses traditional societal values would be beneficial.

The most successful preventive measures within the field of medicine have come from community-wide public health programs (e.g., campaigns against smoking) and from programs that detect individual vulnerabilities (e.g., individual monitoring of blood pressure). Studies of adult antisocial behavior reveal the contribution of broad cultural factors and constellations of individual biopsychosocial vulnerabilities. Prevention programs must recognize and address both kinds of factors.

RELIGIOUS OR SPIRITUAL PROBLEM

A religious or spiritual problem can bring the person to the psychiatrist under one of several circumstances. For example, a person may begin to question his or her faith and choose not to discuss the problem with a spiritual advisor. Or a person may wish to convert to a new faith in order to marry or to create harmony in a marriage in which husband and wife are of different faiths.

Psychiatrists must enable and assist patients to distinguish religious thought or experience from psychopathology and, if this is a problem, encourage patients to work through the issues independently or with assistance. Religious imagery may be recognized in mental illness when persons state they believe they have been commanded by God to take a dangerous or grandiose action.

Religious experience may factor into a person’s life in unexpected ways as in the following case. A midcareer male surgeon who was very successful but long overcommitted to his private practice and his academic responsibilities revealed to his often-neglected wife that, at age 9 years, he was approached by his religious leader to get close physically and ultimately engaged in sexual acts over several years. Believing it was his fault, he never told anyone and decided never to have children. After telling his wife about the experience, they engaged in family therapy to work through the stresses the confession produced in their marriage.
Cults

Recently, cults have appeared to be less popular and less attractive to naïve late adolescents and young adults seeking assistance in discovering who they are as they struggle to develop more mature relationships with their parents. Cults are led by charismatic leaders, often out of control themselves, with inappropriate and often unethical values but purporting to offer acceptance and guidance to troubled followers. Cult members are strongly controlled and forced to dissolve allegiance to family and others to serve the cult leader’s directives and personal needs. These young members often come from educated families who then seek professional help in persuading their children to leave the cult and enter deprogramming therapy to restore personal psychological stability to the former cult members. Deprogramming and adjustment back into family, society, and an independent life are time intensive and long term with resultant posttraumatic stress disorder (PTSD), which must be recognized and treated.

ACCULTURATION PROBLEM

Acculturation is the process whereby a person from one culture undergoes a change in manner, customs, and dress among others to adapt to a different culture. It leads to assimilation in which the person has identified with the new culture, usually without conflict or ambivalence. In some cases, however, major cultural change can evoke severe distress, termed culture shock. This condition arises when individuals suddenly find themselves in a new culture in which they feel completely alien. They may also feel conflict over which lifestyles to maintain, change, or adopt. Children and young adult immigrants often adapt more easily than do middle-aged and elderly immigrants. Younger immigrants often learn the new language more easily and continue to mature in the new culture, but those who are more senior, having had more stability and unchanging routines in their former culture, struggle more to adapt. Culture shock from immigration clearly differs from the restless and continuous moving of psychiatric patients secondary to their illness.

Culture shock can occur within a person’s own country with geographic, school, and work changes, such as joining the military, experiencing school busing, moving across country, or moving to a vastly different neighborhood or from a rural area to a metropolis. Reactive symptoms, which are understandable, include anxiety, depression, isolation, fear, and a sense of loss of identity as the person adjusts. If the person is part of a family or group making this transition and the move is positive and planned, stress can be lower. Furthermore, if selected cultural mores can be safely maintained as persons integrate into the new culture, stress is also minimized.

Constant geographic moves because of chosen work opportunities or necessity involve a large proportion of workers in the United States. Joining activities in the new community and actively trying to meet neighbors and coworkers can lessen the culture shock.
An 18-year-old, first-year female college student offered an academic scholarship by a small Southern college with a major in her field of interest realized on her return home to the Midwest for winter break that she felt like a misfit among her dorm peers. They were friendly yet generally kept their distance from her after class. At home, she discussed her experiences with high school friends, who replied that they had heard about such cultural dissonance from peers at their Midwestern colleges. The student returned to college feeling that it was not her fault or imagination and slowly began to reach out more assertively to her peers so they could get to know her beyond stereotypical beliefs and so she could do the same.

**Brainwashing.** First practiced by the Chinese Communists on American prisoners during the Korean War, *brainwashing* is the deliberate creation of culture shock. Individuals are isolated, intimidated, and made to feel different and out of place to break their spirits and destroy their coping skills. When a person appears mentally weak and helpless, the aggressors impose new ideas on them that they would never have accepted in their normal state. As with those involved in cults, on release and return to their homes, brainwashed individuals with PTSD require deprogramming treatment, including reeducation and ongoing supportive psychotherapy, both on an individual and group basis. Treatment is usually long term to rebuild healthy self-esteem and coping skills. (See also Section 27.4: Disaster Psychiatry.)

**Prisoners of War and Torture Victims.** Prisoners who survive war or torture experiences do so because of personal inner strengths developed in their earlier lives, beginning within their emotionally strong and caring families; if they come from troubled families, they are more likely to commit suicide during imprisonment and torture. Prisoners must constantly cope with ongoing anxiety, fear, isolation from known lives, and complete loss of all control over their lives. Those who appear to cope best believe they must survive for a reason (e.g., to tell others what they experienced or to find and return to loved ones). Prisoners who cope best describe living simultaneously on two levels—coping in the here and now to survive the situation while maintaining constant mental connections to their past values and experiences and those important to them.

Beyond the surviving prisoner’s personal difficulties, including PTSD disorder, if and when his or her survival behavior continues, his or her family may be affected by the surviving prisoner’s inordinate fear of police and strangers, overprotection and overburdening of children to replace those significant others lost, lack of sharing of the past, continued isolation from current communities, or inappropriate expressed anger. Thus, another generation (i.e., children of survivors) can be affected in their personal development and psychological functioning and may require psychiatric evaluation and treatment. (See also Chapter 11, Trauma and Stressor-Related Disorder, for further discussion of these topics).
A 75-year-old, Catholic, female survivor of the Pawiak prison in Warsaw, Poland, and then of a concentration camp after her capture as a member of the underground in World War II stated that she had wanted to become a painter. In camp, she carved the Madonna and Child on her toothbrush and sent it home to her mother. She made other clandestine carvings for several women in her barracks to send home to their families, which pleased everyone. After the war, she became a well-known sculptress with exhibits throughout Europe. Many of her art pieces taught people about suffering and respect for others who are of different religions and cultures.

PHASE OF LIFE PROBLEM

Phase of life problems may occur at any point along the life cycle: the first day of school as a child, the divorce of a parent during adolescence, starting college as a young adult, marriage, having children, illness, caring for aged parents, and many others. Although, on some level, adults recognize that life events will intrude on expected plans in the course of a lifetime, unexpected, multiple, major negative occurrences, especially if they are chronic, overwhelm a person’s ability to recover and function constructively. Common phase of life problems include relationship changes, such as a changed significant personal relationship or its loss, job crises, and parenthood.

Because of sex role socialization and consequent cultural expectations, whereas men appear externally better able to handle these phases of life problems, women, people with lower SES, and minority group members appear more vulnerable to negative experiences, perhaps because they feel less empowered psychologically. Major life changes precipitate distress in the form of anxiety and depressive symptoms, an inability to express reactive emotions directly, and often difficulties in coping with ongoing or changed life responsibilities.

Individuals with positive attitudes, strong family and personal relationships, and mature defense mechanisms and coping styles, including basic trust in self and others, good verbal communication skills, a capacity for creative and positive thinking, and the ability to be flexible, reliable, and energetic, appear to be best able to cope with phase of life problems. Furthermore, a capacity for sublimation; adequate financial and work status; solid values; and healthy, feasible goals can enable people to face, accept, and deal realistically with expected and unexpected life problems and changes.

NONCOMPLIANCE WITH TREATMENT

Compliance is the degree to which a patient carries out the recommendations of the treating physician. It is fostered when the doctor–patient relationship is a positive one, but even in those circumstances, the patient may be reluctant to comply with a physician’s advice. In psychiatry, a major concern is medication noncompliance, which may result from discomforting side effects, expense, personal value judgments, and denial of illness, among many others. This category should be used only when the problem is sufficiently severe to warrant independent clinical attention.

RELATIONAL PROBLEMS
An adult’s psychological health and sense of well-being depend to a significant degree on the quality of his or her important relationships—that is, on patterns of interaction with a partner and children, parents and siblings, and friends and colleagues. Problems in the interaction between any of these significant others can lead to clinical symptoms and impaired functioning among one or more members of the relational unit. Relational problems may be a focus of clinical attention (1) when a relational unit is distressed and dysfunctional or threatened with dissolution and (2) when the relational problems precede, accompany, or follow other psychiatric or medical disorders. Indeed, other medical or psychiatric symptoms can be influenced by the relational context of the patient. Conversely, the functioning of a relational unit is affected by a member’s general and other medical or psychiatric illness. Relational disorders require a different clinical approach than other disorders. Instead of focusing primarily on the link between symptoms, signs, and the workings of the individual mind, the clinician must also focus on interactions between the individuals involved and how these interactions are related to the general and other medical or psychiatric symptoms in a meaningful way.

**Definition**

Relational problems are patterns of interaction between members of a relational unit that are associated with significantly impaired functioning in one or more individual members. Thus one may have parent–child problems, sibling-related problems, or other dyad or triad impairments. At times the entire unit such as the family itself, may be dysfunctional.

**Epidemiology**

No reliable figures are available on the prevalence of relational problems. They can be assumed to be ubiquitous; however, most relational problems resolve without professional intervention. The nature, frequency, and effects of the problem on those involved are elements that must be considered before a diagnosis of relational problem is made. For example, divorce, which occurs in just under 50 percent of marriages, is a problem between partners that is resolved through the legal remedy of divorce and need not be diagnosed as a relational problem. If the persons cannot resolve their disputation and continue to live together in a sadomasochistic or pathologically depressed relationship with unhappiness and abuse, then they should be so labeled. Relationship problems between involved persons that cannot be resolved by friends, family, or clergy require professional intervention by psychiatrists, clinical psychologists, social workers, and other mental health professionals.

**Relational Problem Related to a Mental Disorder or General Medical Condition**

When a family member is ill either from a psychiatric or medical illness, there are reverberations throughout the family unit. Studies indicate that whereas satisfying
relationships may have a health-protective influence, relationship distress tends to be associated with an increased incidence of illness. The influence of relational systems on health has been explained through psychophysiological mechanisms that link the intense emotions generated in human attachment systems to vascular reactivity and immune processes. Thus, stress-related psychological or physical symptoms can be an expression of family dysfunction.

Adults must often assume responsibility for caring for aging parents while they are still caring for their own children, and this dual obligation can create stress. When adults take care of their parents, both parties must adapt to a reversal of their former roles, and the caretakers not only face the potential loss of their parents but also must cope with evidence of their own mortality.

Some caretakers abuse their aging parents, a problem that is now receiving attention. Abuse is most likely to occur when the caretaking offspring have substance abuse problems, are under economic stress, and have no relief from their caretaking duties or when the parent is bedridden or has a chronic illness requiring constant nursing attention. More women are abused than men, and most abuse occurs in persons older than age 75 years.

The development of a chronic illness in a family member stresses the family system and requires adaptation by both the sick person and the other family members. The person who has become sick must frequently face a loss of autonomy, an increased sense of vulnerability, and sometimes a taxing medical regimen. The other family members must experience the loss of the person as he or she was before the illness, and they usually have substantial caretaking responsibility—for example, in debilitating neurological diseases, including dementia of the Alzheimer’s type, and in diseases such as AIDS and cancer. In these cases, the whole family must deal with the stress of prospective death as well as the current illness. Some families use the anger engendered by such situations to create support organizations, increase public awareness of the disease, and rally around the sick member. But chronic illness frequently produces depression in family members and can cause them to withdraw from or attack one another. The burden of caring for ill family members falls disproportionately on the women in a family—mothers, daughters, and daughters-in-law.

Chronic emotional illness also requires major adaptations by families. For instance, family members may react with chaos or fear to the psychotic productions of a family member with schizophrenia. The regression, exaggerated emotions, frequent hospitalizations, and economic and social dependence of a person with schizophrenia can stress the family system. Family members may react with hostile feelings (referred to as expressed emotion) that are associated with a poor prognosis for the person who is sick. Similarly, a family member with bipolar I disorder can disrupt a family, particularly during manic episodes.

Family devastation can occur when illness (1) suddenly strikes a previously healthy person, (2) occurs earlier than expected in the life cycle (some impairment of physical capacities is expected in old age, although many older persons are healthy), (3) affects the economic stability of the family, and (4) when little can be done to improve or ease the condition of the sick family member.

Parent–Child Relational Problem
Parents differ widely in sensing the needs of their infants. Some quickly note their child’s moods and needs; others are slow to respond. Parental responsiveness interacts with the children’s temperament to affect the quality of the attachment between child and parent. The diagnosis of parent–child relational problem applies when the focus of clinical attention is a pattern of interaction between parent and child that is associated with clinically significant impairment in individual or family functioning or with clinically significant symptoms. Examples include impaired communication, overprotection, and inadequate discipline.

Research on parenting skills has isolated two major dimensions: (1) a permissive–restrictive dimension and (2) a warm and accepting versus a cold and hostile dimension. A typology that separates parents on these dimensions distinguishes among authoritarian (restrictive and cold), permissive (minimally restrictive and accepting), and authoritative (restrictive as needed but also warm and accepting) parenting styles. Children of authoritarian parents tend to be withdrawn or conflicted; those of permissive parents are likely to be more aggressive, impulsive, and low achievers; and children of authoritative parents seem to function at the highest level, socially and cognitively. Yet, switching from an authoritarian to a permissive mode may create a negative reinforcement pattern.

Difficulties in many situations stress the usual parent–child interaction. Substantial evidence indicates that marital discord leads to problems in children, from depression and withdrawal to conduct disorder and poor performance at school. This negative effect may be partly mediated through triangulation of the parent–child relationships, which is a process in which conflicted parents attempt to win the sympathy and support of their child, who is recruited by one parent as an ally in the struggle with the partner. Divorces and remarriages stress the parent–child relationship and may create painful loyalty conflicts. Stepparents often find it difficult to assume a parental role and may resent the special relationship that exists between their new marital partner and the children from that partner’s previous marriages. The resentment of a stepparent by a stepchild and the favoring of a natural child are usual reactions in a new family’s initial phases of adjustment. When a second child is born, both familial stress and happiness may result, although happiness is the dominant emotion in most families. The birth of a child can also be troublesome when parents had adopted a child in the belief that they were infertile. Single-parent families usually consist of a mother and children, and their relationship is often affected by financial and emotional problems.

Other situations that can produce a parent–child problem are the development of fatal, disabling, or chronic illness, such as leukemia, epilepsy, sickle-cell anemia, or spinal cord injury, in either the parent or child. The birth of a child with congenital defects, such as cerebral palsy, blindness, or deafness, may also produce parent–child problems. These situations, which are not rare, challenge the emotional resources of those involved. Parents and the child must face present and potential loss and must adjust their day-to-day lives physically, economically, and emotionally. These situations can strain the healthiest families and produce parent–child problems not only with the sick person but also with the unaffected family members. In a family with a severely sick child, parents may resent, prefer, or neglect the other children because the ill child requires so much time and attention.

Parents with children who have emotional disorders face particular problems, depending on the child’s illness. In families with a child with schizophrenia, family treatment is beneficial and improves the social adjustment of the patient. Similarly,
family therapy is useful when a child has a mood disorder. In families with a substance-abusing child or adolescent, family involvement is crucial to help control the drug-seeking behavior and to allow family members to verbalize the feelings of frustration and anger that are invariably present.

Normal developmental crises can also be related to parent–child problems. For instance, adolescence is a time of frequent conflict as the adolescent resists rules and demands increasing autonomy and at the same time elicits protective control by displaying immature and dangerous behavior.

The parents of sons ages 18, 15, and 11 years presented with distress about the behavior of their middle child. The family had been cohesive with satisfactory relationships among all members until 6 months before this consultation. At that time, the 15-year-old son began seeing a girl from a comparatively unsupervised household. Frequent arguments had developed between parents and son regarding going out on school nights, curfews, and neglect of schoolwork. The son’s combativeness and lowered academic achievement upset his parents a great deal. They had not experienced similar conflicts with their oldest child. The adolescent, however, maintained a good relationship with his siblings and friends, did not have behavior problems at school, continued to participate on the school basketball team, and was not a substance user.

Day Care Centers. Quality of care during the first 3 years of life is crucial to neuropsychological development. The National Institute of Child Health and Human Development does not consider day care harmful to children, especially when the caregivers and day care teachers provide consistent, empathetic, nurturing care. Not all day care centers can meet that level of care, however, especially those located in poor urban areas. Children receiving less than optimal caring exhibit decreased intellectual and verbal skills that indicate delayed neurocognitive development. They may also become irritable, anxious, or depressed, which interferes with the parent–child bonding experience, and they are less assertive and less effectively toilet trained by the age of 5 years.

Currently, more than 55 percent of women are in the workforce, many of whom have no choice but to place their children in day care centers. Close to 50 percent of entering medical students are women; few medical centers, however, make adequate provisions for on-site day care centers for their students or staff. Similarly, corporations need to provide on-site, high-quality care for the children of their employees. Not only will that approach benefit the children, but also corporate economic benefits will accrue as a result of reduced absenteeism, increased productivity, and happier working mothers. Such programs have the added benefit of decreasing stresses on marriages.

Partner Relational Problem
Partner relational problems are characterized by negative communication (e.g., criticisms), distorted communication (e.g., unrealistic expectations), or noncommunication (e.g., withdrawal) associated with clinically significant impairment in individual or family functioning or symptoms in one or both partners.

When persons have partner relational problems, psychiatrists must assess whether a patient’s distress arises from the relationship or from a mental disorder. Mental disorders are more common in single persons—those who never married or who are widowed, separated, or divorced—than among married persons. Clinicians should evaluate developmental, sexual, and occupational and relationship histories, for purposes of diagnosis. (Couples therapy is discussed in Chapter 28, Section 28.4.)

Marriage demands a sustained level of adaptation from both partners. In a troubled marriage, a therapist can encourage the partners to explore areas such as the extent of communication between the partners, their ways of solving disputes, their attitudes toward child bearing and child rearing, their relationships with their in-laws, their attitudes toward social life, their handling of finances, and their sexual interaction. The birth of a child, an abortion or miscarriage, economic stresses, moves to new areas, episodes of illness, major career changes, and any situations that involve a significant change in marital roles can precipitate stressful periods in a relationship. Illness in a child exerts the greatest strain on a marriage, and marriages in which a child has died through illness or accident more often than not end in divorce. Complaints of lifelong anorgasmia or impotence by marital partners usually indicate intrapsychic problems, although sexual dissatisfaction is involved in many cases of marital maladjustment.

Adjustment to marital roles can be a problem when partners are from different backgrounds and have grown up with different value systems. For example, members of low SES groups perceive a wife as making most of the decisions in the family, and they accept physical punishment as a way to discipline children. Middle-class persons perceive family decision-making processes as shared, with the husband often being the final arbiter, and they prefer to discipline children verbally. Problems involving conflicts in values, adjustment to new roles, and poor communication are handled most effectively when therapist and partners examine the couple’s relationship, as in marital therapy.

Epidemiological surveys show that unhappy marriages are a risk factor for major depressive disorder. Marital discord also affects physical health. For example, in a study of women age 30 to 65 years with coronary artery disease, marital stress worsened the prognosis 2.9 times for recurrent coronary events. Marital conflict was also associated with a 46 percent higher relative death risk among female patients having hemodialysis and with elevations in serum epinephrine, norepinephrine, and corticotrophin levels in both men and women. In one study, high levels of hostile marital behavior were associated with slower healing of wounds, lower production of proinflammatory cytokines, and higher cytokine production in peripheral blood. Overall, women show greater psychological and physiological responsiveness to conflict than men.

Physician Marriages. Physicians have a higher risk of divorce than other occupational groups. The incidence of divorce among physicians is about 25 to 30 percent. Specialty choice influenced divorce. The highest rate of divorce occurred in psychiatrists (50 percent) followed by surgeons (33 percent) and internists, pediatricians, and pathologists (31 percent). The average age at first marriage was 26
years among all groups.
It is not clear why physicians are at high risk for divorce. Factors implicated include the stresses of dealing with dying patients, making life-and-death decisions, working long hours, and the constant risk of malpractice litigation. Such stressors may predispose physicians to a variety of emotional ills, with the most common being depression and substance abuse, including alcoholism. Such persons generally cannot deal with the complex interactions required to maintain successful long-term relationships of any kind, and marriage requires the most interpersonal skills of all.

Sibling Relational Problem

Sibling relationships tend to be characterized by competition, comparison, and cooperation. Intense sibling rivalry can occur with the birth of a child and can persist as the children grow up, compete for parental approval, and measure their accomplishments against one another. Alliances between siblings are equally common. Siblings may learn to protect one another against parental control or aggression. In households with three children, one pair tends to become closely involved with one another, leaving the extra child in the position of outsider.

Relational problems can arise when siblings are not treated equally; for instance, when one child is being idealized while another is cast in the role of the family scapegoat. Differences in gender roles and expectations expressed by the parents can underlie sibling rivalry. Parent–child relationships also are dependent on personality interactions. A child’s resentment directed at a parental figure or a child’s own disavowed dark emotions can be projected onto a sibling and can fuel an intense hate relationship.

A child’s general, other medical or psychiatric condition always stresses the sibling relationships. Parental concern and attention to the sick child can elicit envy in the siblings. In addition, chronic disability can leave the sick child feeling devalued and rejected by siblings, and the latter may develop a sense of superiority and may feel embarrassed about having a disabled sister or brother. Twin relationships have become an area of increasing study. Preliminary data show that twins are more likely to be cooperative than competitive. Whether or not identical twins should be dressed differently during their toddler years in an effort to ensure a separate identity is open to question as is the issue of whether or not they should be in separate classrooms when they begin school.

Other Relational Problems

People, across the life cycle, may become involved in relational problems with leaders and others in their communities at large. In such relationships, conflicts are common and can bring about stress-related symptoms. Many relational problems of children occur in the school setting and involve peers. Impaired peer relationships can be the chief complaint in attention-deficit or conduct disorders, as well as in depressive and other psychiatric disorders of childhood, adolescence, and adulthood.

Racial, ethnic, and religious prejudices and ignorance cause problems in interpersonal relationships. In the workplace and in communities at large, sexual harassment is often a combination of inappropriate sexual interactions; inappropriate displays of abuse of power and dominance; and expressions of negative gender stereotypes, primarily
toward women and gay men, although it is also geared toward children and adolescents of both sexes.

Bosco SM, Harvey D. Effects of terror attacks on employment plans and anxiety levels of college students. College Student J. 2003;37:438–446.
Violence is an important public health concern in the United States. The majority of Americans will fall victim to a violent crime during their lifetime. Besides mortality, violence creates a heavy toll in medical costs, disability, and psychiatric sequelae.

Assault can be viewed in the context of two variables. The first involves who is being assaulted, and the second is where the assault occurs. With these parameters assault can be classified into several categories, the most common being violent crimes (aggravated and simple assault, robbery), rape, domestic violence, workplace violence, and torture. The prevalence of the different types of assaults is most often reported by two different data collection systems: (1) the Federal Bureau of Investigation’s Uniform Crime Report (UCR), which collects reported crime information from local law enforcement agencies and (2) the Bureau of Justice Statistics’ National Crime Victimization Survey (NCVS), which generates estimates of the likelihood of victimization from different types of assaults.

**VIOLENT CRIME**

*Violent crime* is defined as murder and nonnegligent manslaughter, forcible rape, robbery, and aggravated assault. These categories exclude simple assault, which is defined as an assault not involving a weapon and in which the victim was not seriously harmed. Simple assault has also been defined as stalking, intimidating, coercing, or hazing.

**Prevalence**

In 2011, the UCR reported over 1.2 million violent crimes occurred within the United States. Aggravated assault accounted for approximately 750,000 of this total, and robberies accounted for approximately 350,000. Ten-year trends show a decrease of 16 percent in violent crime since 2002. Aggravated assault was the most reported violent crime (62 percent), followed by robbery (29 percent), forcible rape (7 percent), and murder (1 percent). Also in 2011, firearms were found to be used in 21 percent of aggravated assaults and 41 percent of robberies.

**Risk Factors**

Gender and age play large roles in the rate of risk for assaults of all types. Males between the ages of 15 and 34 years are more likely to be assaulted than females and are 11 times more likely to be assaulted by strangers than by someone they know.
Research suggests that race is an important factor as well, with African Americans being at greater risk of violence and having a death rate that is four or five times higher than age-matched whites during aggravated assaults. The NCVS found that males and females in households earning less than $15,000 in annual income were twice as likely to be robbed and 1.5 times as likely to suffer a physical assault. Homelessness has also been shown to be a factor in increased physical assaults. Finally, substance abuse has been shown in multiple studies to increase the risk of victimization.

RAPE

Rape is the forceful coercion of an unwilling victim to engage in a sexual act, usually sexual intercourse, although anal intercourse and fellatio can also be acts of rape. The legal definition of rape varies from state to state. Some states strictly define rape, whereas other states describe any sex crime as varying degrees of sexual misconduct or sexual assault. Rape can occur between married partners and between persons of the same sex. Forced acts of fellatio and anal penetration, although they frequently accompany rape, are legally considered sodomy.

In some states the definition of rape has been changed to substitute the word person for female. In most states, male rape is legally defined as sodomy. Like other violent crimes, sexual assault is declining; however, every 2 minutes someone in the United States is sexually assaulted. Although much of the population believes in the stereotype of the culprit being a stranger, research has shown that only about 26 percent of all rapes are committed by a stranger.

Prevalence

Unfortunately, accurate statistics are difficult to obtain because of underreporting and unacknowledgment. The Rape, Abuse, and Incest National Network (RAINN) estimates that over half of rapes go unreported. Although in the United States, rapes have fallen in number since 1993, currently there is an average of 207,754 rapes and sexual assaults per year. RAINN estimates that 1 in 6 US women and 1 in 33 US men are victims of sexual assault.

In addition to being underreported, there are many rapes that go unacknowledged by the victim, who often refer to the assault in more benign terms such as a misunderstanding, despite the fact that it meets the legal definition of rape. Research has reported that this percentage is substantial; more than 50 percent of sexual assaults may go unacknowledged and, thus, unreported. Research has further revealed that victims who fail to acknowledge having been raped usually believe that rape involves two strangers and greater force, as opposed to the views of those who acknowledge their having been sexually assaulted.

Statistics show that most men who commit rapes are between 25 and 44 years of age; 51 percent are white and tend to rape white victims, 47 percent are black and tend to rape black victims, and the remaining 2 percent come from all other races. Alcohol is involved in 34 percent of all forcible rapes. Homosexual rape is much more frequent
among men than among women and occurs frequently in closed institutions such as prisons and maximum security hospitals.

**Risk Factors**

Although women are usually the victim of rape and sexual assault, greater than 10 percent of victims are estimated to be men. Furthermore, most experts believe that men underreport more than women. Nevertheless, young women have four times the risk of any group of becoming a victim of sexual assault. Persons who are raped can be of any age. Cases have been reported in which the victims were as young as 15 months and as old as 82 years. However, 80 percent of all rape victims are under the age of 30 years and the Bureau of Justice statistics indicate that women age 16 to 24 years are at the greatest risk for rape in the United States. Having been a victim of childhood abuse or previous assault increases the likelihood of further assault of all types. Most rapes are premeditated; about half are committed by strangers and half by men known, to varying degrees, by the victims.

The Violence Against Women Act has had an important role to play in reducing rape and other types of violence (*Table 26-1*).

| Table 26-1 | Violence Against Women Act (VAWA) |
Perpetrators

In general, rape is considered a crime of power and aggression, not one of sexuality. Male rapist can be categorized into separate groups: sexual sadists, who are aroused by the pain of their victims; exploitive predators, who use their victims as objects for their gratification in an impulsive way; inadequate men, who believe that no woman would voluntarily sleep with them and who are obsessed with fantasies about sex; and men for whom rape is a displaced expression of anger and rage. Seven percent of all rapes are perpetrated by close relatives of the victim; 10 percent of rapes involve more than one attacker.

Rape often accompanies another crime. Rapists always threaten victims, with fists, a knife, or a gun, and frequently harm them in nonsexual ways as well. Victims can be beaten, wounded, and killed.

In cases of male or homosexual rape, the dynamics are identical to those of heterosexual rape. The crime enables the rapist to discharge aggression and to aggrandize himself. The victim is usually smaller than the rapist, is always perceived as
passive and unmanly (weaker), and is used as an object. A rapist selecting male victims may be heterosexual, bisexual, or homosexual. The most common act is anal penetration of the victim; the second most common is fellatio.

SEXUAL COERCION

*Sexual coercion* is a term used for incidents in which a person dominates another by force or compels the other person to perform a sexual act.

STALKING

*Stalking* is defined as a pattern of harassing or menacing behavior coupled with a threat to do harm. The first antistalking law was passed in 1990 in California. Now most states prohibit stalking, although some will not intervene unless an act of violence has occurred. In states with stalking laws, the person can be arrested on the basis of a pattern of harassment and can be charged with either a misdemeanor or felony. Some stalkers continue the activity for years; others, for only a few months. The court may mandate that stalkers undergo counseling sessions. The best means of deterrent is to report all stalkers to law enforcement agencies. Most stalkers are men, but women who stalk are just as likely as men to attack their victims violently.

SEXUAL HARASSMENT

Sexual harassment refers to sexual advances, requests for sexual favors, or verbal or physical conduct of a sexual nature—all of which are unwelcomed by the victim. In more than 95 percent of cases the perpetrator is a man and the victim is a woman. If a man is being harassed, it is almost always by another man. A woman sexually harassing a man is an extremely rare event. The victim of harassment reacts to the experience in various ways. Some blame themselves and become depressed; others become anxious and angry. In general, harassment most commonly occurs in the workplace, and many organizations have developed procedures to deal with the problem. All too often, however, the victim is unwilling to step forward and lodge a complaint because of fear of retribution, of being humiliated, of being accused of lying, or ultimately of being fired from the job.

The types of behaviors that make up sexual harassment are broad. They include abusive language, requests for sexual favors, sexual jokes, staring, ogling, and giving massages, among others.

To reduce harassment, organizations may distribute educational material. Employees are obligated to investigate every complaint, which most often are addressed to the Equal Employment Opportunity Commission. Appropriate organizational responses range from a written warning to firing the offender.

DOMESTIC VIOLENCE

*Domestic violence* (also known as *spouse abuse*) is defined as physical assault within the
home in which one spouse is repeatedly assaulted by the other. It has been estimated that domestic violence occurs in one of every four families in the United States. Often domestic violence is broken down into two categories: “high-severity abuse,” which includes being threatened or hurt with a weapon, burned, choked, hit, or kicked, resulting in broken bones and head or internal injuries; and “low-severity abuse,” which includes being slapped, hit, or kicked without injury, but also could include bruising, minor cuts, and sprains.

Unfortunately, domestic violence does not end when a woman becomes pregnant. In fact, the surgeon general’s office has identified pregnancy as a high-risk period for battering; 15 to 25 percent of pregnant women are physically abused while pregnant, and the abuse often results in birth defects. In addition, pregnant and recently pregnant women are more likely to die from homicide than any other cause.

Some husband-beating wives have also been reported. Husbands complain of fear of ridicule if they expose the problem; they fear charges of counterassault and often feel unable to leave the situation because of financial difficulties. Husband abuse also been reported when a frail, elderly man is married to a much younger woman.

Prevalence
Estimates of the prevalence of domestic violence in the United States vary widely, and many studies include psychological or emotional abuse. Worldwide estimates state that one in every three women has experienced some form of physical or sexual abuse from a domestic partner. One study based on several internal medicine practices found that approximately 6 percent of women had experienced domestic violence in the year prior to presentation. It was found that of the women currently experiencing abuse, 49 percent experience high-severity abuse and 51 percent experience low-severity abuse.

Risk Factors
Domestic violence occurs in families of every racial and religious background and in all socioeconomic strata. Any person in an intimate relationship can be at risk. It is most frequently found in families with problems of substance abuse, particularly alcohol and crack abuse. Another risk factor is a history of childhood abuse. About 50 percent of battered wives grew up in violent homes and their most common trait is dependence. Abusive men are also likely to have come from violent homes where they witnessed wife beating or were abused themselves as children.

Women face risks when they leave an abusive husband; they have a 75 percent greater chance of being killed by their batterers than women who stay. New York State prepared a physician reference card to alert and guide doctors about domestic violence (Table 26-2).

Physician Reference Card
RECOGNIZING AND TREATING VICTIMS OF DOMESTIC VIOLENCE BASED ON THE AMERICAN MEDICAL ASSOCIATION’S
DIAGNOSTIC AND TREATMENT GUIDELINES ON DOMESTIC VIOLENCE

If you treat women, whether in private practice or a hospital setting, you are almost certainly treating some patients who are victims of domestic violence.

The following decision tree is designed to help you assess a patient’s risk of domestic violence and offer appropriate help to those in need of it.

Identifying Victims of Domestic Violence

Although many women who are victims of abuse will not volunteer any information, they will discuss it if asked simple, direct questions in a nonjudgmental way and in a confidential setting. The patient should be interviewed alone, without her partner present.

You may want to offer a statement such as: “Because violence is so common in many women’s lives, I’ve begun to ask about it routinely.” Then you can ask a direct question, such as: “At any time, has your partner hit, kicked, or otherwise hurt or frightened you?”

IF PATIENT ANSWERS YES, THE FOLLOWING STEPS ARE SUGGESTED:

1. Encourage her to talk about it:
   “Would you like to talk about what has happened to you?”
   “How do you feel about it?”
   “What would you like to do about this?”

2. Listen nonjudgmentally:
   This serves both to begin the healing process for the woman and to give you an idea of what kind of referrals she needs.

3. Validate:
   Victims of domestic violence are frequently not believed, and the fear they report is minimized. The physician can express support through simple statements such as:
   - “You are not alone.”
   - “You don’t deserve to be treated this way.”
   - “You are not to blame.”
   - “You are not crazy.”
   - “What happened to you is a crime.”
   - “Help is available for you.”

4. Document:
   - The patient’s complaints and symptoms as well as the results of the observation and assessment. (Complaints should be described in the patient’s own words whenever possible.)
   - The patient’s complete medical and trauma history and relevant social history.
   - A detailed description of the injuries, including type, number, size, location, resolution, possible causes, and explanations given.
   - An opinion on whether the injuries were inconsistent with the patient’s explanation.
   - Results of all pertinent laboratory and other diagnostic procedures.
   - Color photographs and imaging studies, if applicable.
   - If the police are called, the name of the investigating officer and any action taken (the police should be called only if the patient requests this or exhibits a reportable injury).
   - Child abuse and neglect are reportable offenses. If you suspect that children in the patient’s home are also being abused, you are mandated to report the situation to the Department of Social Services.

5. Assess the danger to your patient:
   Assess your patient’s safety before she leaves the medical setting. The most important determinants of risk are the woman’s level of fear and her appraisal of her immediate and future safety. Discussing the following indicators with the patient can help you determine if she is in escalating danger:
   - an increase in the frequency or severity of the assaults
   - increasing or new threats of homicide or suicide by the partner
   - threats to her children
   - the presence or availability of a firearm

6. Provide appropriate treatment referral and support:
   - Treat the patient’s injuries as indicated. In prescribing medication, keep in mind that medications which hinder the patient’s ability to protect herself or to flee from a violent partner may endanger her life.
   - If your patient is in imminent danger, determine if she has friends or family with whom she can stay. If this is not an option, ask if she wants immediate access to a shelter for battered women. If none is available, can she be admitted to the hospital?
   - If she doesn’t need immediate access to a shelter, offer written information about shelters and other community resources. Remember that it may be dangerous for the woman to have these in her possession. Don’t insist that she take them if she is reluctant to do so.
   - Give your patient the telephone number of the local domestic violence hotline or the toll-free Domestic Violence hotline. It may be safer for your patient if you write the number on a prescription blank or an appointment card. You may wish to give her the opportunity to call from a private phone in your office.
Perpetrators

The perpetrators of domestic violence come from all races and socioeconomic levels. However, having been a victim of abuse or witnessing abuse in the home increases the risk of someone becoming an abuser. Alcohol abuse is usually involved in most offenses. The act of abuse itself is reinforcing; once a man has beaten his wife, he is likely to do so again. Many abusers are noted to be charming in public but cruel to their intimates.

Abusive husbands tend to be immature, dependent, and nonassertive and to suffer from strong feelings of inadequacy. The husband’s aggression is bullying behavior designed to humiliate their wives and to build up their own low self-esteem. Impatient, impulsive, abusive husbands physically displace aggression provoked by others onto their wives. The abuse most likely occurs when a man feels threatened or frustrated at home, at work, or with his peers. The dynamics include identification with an aggressor (father, boss), testing behavior (“Will she stay with me, no matter how I treat her?”), distorted desires to express manhood, and dehumanization of women. As with rape, aggression is deemed permissible when a woman is perceived as property.

When an abused wife tries to leave her husband, he often becomes doubly intimidating and threatens to “get” her. If the woman has small children to care for, her problem is compounded. The abusive husband wages a conscious campaign to isolate his wife and make her feel worthless.

Some men feel remorse and guilt after an episode of violent behavior and so become particularly loving. If this behavior gives the wife hope, she remains until the next inevitable cycle of violence.
WORKPLACE VIOLENCE

Acts of violence at work are defined as simple assault, aggravated assault, robbery, rape/sexual abuse, and homicide.

Prevalence

Workplace violence accounts for approximately 15 percent of all violent crimes in the United States. According to the NCVS, in 2009 there were approximately 572,000 acts of violence committed against persons at work. During the same time, over 500 work-related homicides occurred. Approximately 78 percent of workplace assaults did not involve weapons, and 80 percent of workplace homicides involved firearms. With some variation, violent crime in the workplace has decline approximately 35 percent since 2002.

Risk Factors

Gender and race are important risk factors in workplace violence. The workplace violence rate for women has decreased approximately 43 percent since 2002, while the rate for men has decreased approximately 30 percent. Approximately two thirds of all workplace assaults (excluding rape/sexual assault) are committed against men. Workplace crime rates are higher among whites than other races.

An important component of workplace violence is the relationship between the risk of violence and the type of occupation. The NCVS found that police officers are at the highest risk for victimization (78 per 1,000) and constituted 9 percent of all workplace assaults. Other high-risk occupations include security guard (65 per 1,000), correction officer (33 per 1,000), bartender (80 per 1,000), technical/industrial schoolteacher (55 per 1,000), mental health custodial worker (38 per 1,000), gas station attendant (30 per 1,000), and mental health professionals (17 per 1,000).

Perpetrators

There are several distinct characteristics among offenders, of which gender is the most pronounced. As reported by victims, four fifths of all violent workplace crime is committed by men, and this is regardless of the victim’s gender. The race of the offenders is most often white, followed by black, and most of the attacks are interracial. Unlike domestic violence, workplace violence is more often perpetrated by strangers or casual acquaintances than by known intimates. Mental health and teaching are the only fields in which attacks occur more often at the hands of a known perpetrator than by a stranger.

SEQUELAE OF VIOLENCE AND ASSAULT

Survivors of violence have varied reactions, but they are similar to those exposed to other types of trauma. Furthermore, the severity of the sequelae varies with the
individual. However, multiple studies have shown that many of the people who experience violence have decreased physical and mental health, resulting in higher utilization of health care services.

The most common reported sequelae after sexual assault in women are posttraumatic stress disorder (PTSD), mood disorders, substance abuse, eating disorders, and sexual disorders. One of the most protective factors in ameliorating the development of PTSD is social support. Furthermore, the lack of social support and the perception of being treated differently can be quite detrimental to the survivor, causing an increase in PTSD symptoms.

Domestic violence has been associated with depression, anxiety, low self-esteem, substance abuse, sexual dysfunction, functional gastrointestinal disorder, headaches, chronic pain, and multiple somatic symptoms. Physical symptoms associated with current abuse include loss of appetite; frequent or serious bruises; nightmares; vaginal discharge; eating binges or self-induced vomiting; diarrhea; broken bones; sprains or serious cuts; pain in the pelvic or genital area; fainting; abdominal pain; breast pain; frequent or severe headaches; difficulty passing urine; chest pain; problems with sleeping; shortness of breath; and constipation. Many studies have shown that survivors of domestic violence attempt suicide more frequently than those who have not experienced violence.

Substance abuse seems to be a significant factor for both the survivor and the batterer. It is both a risk factor for abuse and a consequence of it.

The relationship between childhood abuse and adult abuse is complex. Childhood abuse is a risk factor for abuse as an adult, and childhood abuse increases both physical and mental health sequelae of adult abuse. Survivors of sexual assault or domestic violence who are older and without a history of childhood abuse have fewer symptoms.

**TREATMENT ISSUES**

**Initial Evaluation**

Many victims of assault initially present to a medical doctor for treatment of their injuries. In emergency departments, patients may often be treated for their injuries without the assault being recognized or addressed. Consequently, it is important to consider any concerning injuries as being a potential stigmata of assault. The patient may initially be avoidant when asked about the cause of injuries that appear related to assault. This may be further complicated by the need to complete specific tasks (i.e., rape kit, photo documentation, reporting of legal concerns) that require the patient to describe and relive the recent assault. It is paramount to build rapport with the patient while continuing to complete a thorough evaluation. To facilitate this process, it is important to reduce the victim’s stress and anxiety regarding discussion of the event. The initial evaluation process should be explained to the patient before beginning. Allowing the patient some say in dictating the pace and content of the interview is preferable to having a patient feel a lack of control over the process. The crime may represent a time when the patient lacked control, and similar feelings in the initial
interview can lead to a triggering of traumatic or anxious responses. Finally, the physician should remain attuned to nonverbal patient responses that signify discomfort and conduct the interview accordingly. Furthermore, when a patient discloses domestic violence, this should be documented in his or her chart for future follow-up and possible future legal documentation.

**Safety**

After an assault, it is imperative that a safety assessment be performed on the victim. The patient needs to be evaluated for suicidal and homicidal ideation as it pertains to the recent assault. The patient’s safety from further assault also needs to be addressed, especially in a setting in which the perpetrator was a loved one or known acquaintance. Finally, the patient needs to be screened for severe psychological symptoms that would cause difficulty in self-care. These would include acute mood deterioration or affective instability, self-destructive behaviors, dissociative symptoms, or psychosis. If the evaluation shows that any of these areas are inadequate to ensure patient safety, then a plan needs to be developed. This plan should provide for the patient’s physical safety and give the patient a place to sleep, recuperate, and eat.

**Hospitalization**

In the event that the patient’s safety cannot be guaranteed, hospitalization of the assault victim may be necessary. Common indications for hospitalization include (1) severe medical injuries, (2) suicidality or homicidality, (3) dissociative or psychotic symptoms, (4) mood instability or affective dysregulation, (5) self-destructive behaviors, and (6) a continued serious threat to the patient’s life or well-being. If the victim is admitted to the hospital, then an individualized multidisciplinary treatment plan should be developed. Safety, milieu therapy, mood stabilization, and medication evaluation are the primary treatment modalities provided in the hospital and reflect the short-stay nature of most psychiatric facilities. Because the assault victim will likely need longer treatment than what can be provided in the hospital, it is important that there is a coordinated inpatient-to-outpatient transition, which psychiatric, medical, and social work issues all being address prior to discharge.

**Legal Issues**

A physician evaluating an assault victim needs to adhere to mandatory reporting requirements for the state in which he or she is practicing. Mandatory reporting of child abuse, abuse of developmentally disabled children, and abuse of the elderly exist in all 50 states. In cases of assault secondary to domestic violence, states do not usually require mandatory reporting. However, many states do require physicians to report serious injuries due to acts of criminal violence. Thus, in the setting of injury secondary to domestic violence, this can sometimes be considered a de facto mandatory reporting situation.
Psychotherapy Treatment

After the patient’s safety has been ensured and the initial evaluation is complete, there are a variety of psychological interventions that can be initiated. Cognitive-behavioral approaches are the most researched techniques demonstrating efficacy. Exposure therapy is a variant of cognitive-behavioral therapy (CBT) that has been shown to help victims emotionally process the assault by decreasing their fear to memories or cues of the event. There is evidence in the literature that brief early CBT may accelerate recovery in victims manifesting acute PTSD. Eye movement desensitization and reprocessing (EMDR) is another alternative treatment for the processing of distressing memories. These individual psychotherapies may be augmented with group psychotherapy, art therapy, dance and movement therapy, music therapy, and body-oriented approaches if they prove beneficial to the patient.

Psychopharmacological Treatment

Although medication is not recommended in the acute treatment of all assault victims, it may be beneficial in certain circumstances. The clinician may decide to medicate a patient with incapacitating anxiety, extreme aggression toward themselves or others, or dissociation or psychoses immediately after the assault. The patient’s safety and the safety of those around the patient will help to decide the need for pharmacologic intervention. Most medication treatment will be initiated much later after the assault as the patient develops symptoms of PTSD, depression, anxiety, obsessive-compulsive disorder, or psychosis. Although medication may be useful in symptom management, they should not be viewed as a replacement for psychotherapy aimed at trauma symptom resolution.

REFERENCES

Reproductive events and processes have both physiological and psychological concomitants. Likewise, psychological states affect reproductive physiology and modulate reproductive events. This chapter examines these bidirectional relationships with the goal of introducing fundamental concepts related to the classic reproductive events, such as menarche, pregnancy, delivery, postpartum, and menopause. The fields of psychiatry and reproductive medicine continue to define the multiple mechanisms by which psyche and soma interact to determine a woman’s gynecological and psychological health. For instance, premenstrual dysphoric disorder—the impairing symptoms and severe mood, cognitive, and behavioral changes that occur in association with the menstrual cycle—exemplifies a somatopsychic disorder in which biological changes occurring in the soma trigger changes in psychological state. In contrast, functional forms of hypothalamic anovulation represent psychosomatic illness that originates in the brain but alters somatic functioning.

**REPRODUCTIVE PHYSIOLOGY**

The physiological processes associated with menarche, menstrual cycling, pregnancy, postpartum, and menopause occur within the context of a woman’s physiological and interpersonal life, interfacing with psychosocial functioning throughout adolescence, young adulthood, midlife, and late life. The fields of psychiatry and reproductive medicine are just beginning to elaborate the multiple mechanisms by which psyche and soma interact to determine a woman’s gynecological and psychological function. This chapter illustrates how reproductive processes interact with psychosocial events and aims ultimately to improve the approach to both gynecologic and psychiatric treatments.

**Menstrual Cycles**

Menstrual cyclicity results directly from ovarian cyclicity. Each ovarian cycle starts with the development of a group or cohort of follicles, one of which becomes dominant. The follicles are composed of an oocyte surrounded by granulosa cells, which, in turn, are surrounded by theca cells.

As shown at the top of Figure 27-1, follicular development is initiated by the hypothalamic release of gonadotropin-releasing hormones (GnRH) at a pulse frequency of approximately one pulse every 90 minutes. GnRH stimulates the release of the pituitary gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). In turn, LH stimulates ovarian theca cells to synthesize and secrete androgens;
FSH induces granulosa cell development, including the enzyme aromatase, which converts the thecally produced androgens to estrogens. In the presence of a constant GnRH pulse frequency of one pulse each 90 minutes, the secretion of LH and FSH in the follicular phase will be regulated primarily by estradiol feedback at the level of the pituitary. Rising estradiol concentrations suppress FSH, thereby limiting the number of follicles that become mature oocytes capable of ovulating.

As illustrated in the middle panel of Figure 27-1, when estradiol concentrations rise exponentially to exceed a critical threshold and remain elevated for at least 36 hours, which is the pattern one fully mature follicle produces, an LH surge is triggered and ovulation (release of the ovum from the follicle sac) ensues approximately 36 hours later. Thereafter, granulosa cells transform into progesterone-secreting luteal cells, and the ovulated follicle is then referred to as the corpus luteum, which secretes progesterone.

Figure 27-1 displays the levels of LH, FSH, estradiol, and progesterone throughout the menstrual cycle and corresponding follicular events. The target tissues for ovarian steroids include the endometrium, whose developmental sequence is illustrated along the bottom panel, and the hypothalamic GnRH pulse generator, whose frequency, as indicated in the top right panel, is slowed dramatically by the combination of estrogen and progesterone secreted during the postovulatory or luteal phase of the menstrual cycle. This inhibition of GnRH is followed by decreased secretion of LH and FSH so that
new follicular development is prevented until the corpus luteum regresses. As progesterone concentrations decline, GnRH pulsatility increases, and gonadotropin, especially FSH, secretion rises. The phases of the menstrual cycle can be termed follicular and luteal in reference to ovarian events or proliferative and secretory in reference to endometrial events.

PREGNANCY

Biology of Pregnancy

The first presumptive sign of pregnancy is the absence of menses for 1 week. Other presumptive signs are breast engorgement and tenderness, changes in breast size and shape, nausea with or without vomiting (morning sickness), frequent urination, and fatigue. A diagnosis can be made 10 to 15 days after fertilization by testing for human chorionic gonadotropin (hCG), which is produced by the placenta. The definitive diagnosis requires a doubling of hCG levels and the presence of fetal heart sounds. Transvaginal ultrasound scanning can reveal a pregnant uterus as early as 4 weeks after fertilization, by visualization of a gestational sac.

Stages of Pregnancy

Pregnancy is commonly divided into three trimesters, starting from the first day of the last menstrual cycle and ending with the delivery of a baby. During the first trimester, the woman must adapt to changes in her body, such as fatigue, nausea and vomiting, breast tenderness, and mood lability. The second trimester is often the most rewarding for women. A return of energy and the end of nausea and vomiting allow women to feel better and experience the excitement of starting to look pregnant. The third trimester is associated with physical discomfort for many women. All systems—cardiovascular, renal, pulmonary, gastrointestinal, and endocrine—have undergone profound changes that can produce a heart murmur, weight gain, exertional dyspnea, and heartburn. Some women require reassurance that those changes are not evidence of disease and that they will return to normal shortly after delivery—generally in 4 to 6 weeks.

Psychology of Pregnancy

Pregnant women undergo marked psychological changes. Their attitudes toward pregnancy reflect deeply felt beliefs about all aspects of reproduction, including whether the pregnancy was planned and whether the baby is wanted. The relationship with the infant’s father, the age of the mother, and her sense of identity also affect a woman’s reaction to prospective motherhood. Prospective fathers also face psychological challenges.

Psychologically healthy women often find pregnancy a means of self-realization. Many women report that being pregnant is a creative act gratifying a fundamental need. Other women use pregnancy to diminish self-doubts about femininity or to
reassure themselves that they can function as women in the most basic sense. Still others view pregnancy negatively; they may fear childbirth or feel inadequate about mothering.

During early stages of their own development, women must undergo the experience of separating from their mothers and of establishing an independent identity; this experience later affects their own success at mothering. If a woman’s mother was a poor role model, a woman’s sense of maternal competence may be impaired, and she may lack confidence before and after her baby’s birth. Women’s unconscious fears and fantasies during early pregnancy often center on the idea of fusion with their own mothers.

Psychological attachment to the fetus begins in utero and, by the beginning of the second trimester, most women have a mental picture of the infant. Even before being born, the fetus is viewed as a separate being, endowed with a prenatal personality. Many mothers talk to their unborn children. Recent evidence suggests that emotional talk with the fetus is related not only to early mother–infant bonding but also to the mother’s efforts to have a healthy pregnancy, for example, by giving up cigarettes and caffeine. According to psychoanalytic theorists, the child-to-be is a blank screen on which a mother projects her hopes and fears. In rare instances, these projections account for postpartum pathological states, such as a mother’s desire to harm her infant, whom she views as a hated part of herself. Normally, however, giving birth to a child fulfills a woman’s need to create and nurture life.

Fathers are also profoundly affected by pregnancy. Impending parenthood demands a synthesis of such developmental issues as gender role and identity, separation or individuation from a man’s own father, sexuality, and, as Erik Erikson proposed, generativity. Pregnancy fantasies in men and wishes to give birth in boys reflect early identification with their mothers as well as the wish to be as powerful and creative as they perceive mothers to be. For some men, getting a woman pregnant is proof of their potency, a dynamic that plays a large part in adolescent fatherhood.

Marriage and Pregnancy

The prospective mother–wife and father–husband must redefine his or her roles as a couple and as an individual. They face readjustments in their relationships with friends and relatives and must deal with new responsibilities as caretakers of the newborn and each other. Both parents may experience anxiety about their adequacy as parents; one or both partners may be consciously or unconsciously ambivalent about the addition of the child to the family and about the effects on the dyadic (two-person) relationship. A husband may feel guilty about his wife’s discomfort during pregnancy and parturition, and some men experience jealousy or envy of the experience of pregnancy. Accustomed to gratifying each other’s dependency needs, the couple must attend to the unremitting needs of a new infant and a developing child. Although most couples respond positively to these demands, some do not. Under ideal conditions, the decision to become a parent and have a child should be agreed on by both partners, but sometimes parenthood is
rationalized as a way to achieve intimacy in a conflicted marriage or to avoid having to deal with other life circumstance problems.

Attitudes Toward the Pregnant Woman. In general, others’ attitudes toward a pregnant woman reflect a variety of factors: intelligence, temperament, cultural practices, and myths of the society and the subculture into which the person was born. Married men’s responses to pregnancy are generally positive. For some men, however, reactions vary from a misplaced sense of pride that they are able to impregnate the woman to fear of increased responsibility and subsequent termination of the relationship. A woman’s risk of abuse by her husband or boyfriend increases during pregnancy, particularly during the first trimester. One study found that 6 percent of pregnant women are abused. Domestic abuse adds significantly to the cost of health care during pregnancy, and abused women are more likely than nonabused controls to have histories of miscarriage, abortion, and neonatal death. The reasons for abuse vary. Some men fear being neglected and not having excessive dependency needs gratified; others may see the fetus as a rival. In most cases, however, one finds a history of abuse before the woman became pregnant.

Same-Sex Partnering, Marriage, and Pregnancy
Some lesbian couples decide that one partner should become pregnant through artificial insemination. Societal attitudes may put stress on this arrangement, but if the two women have a secure relationship, they tend to bond strongly together as a family unit. Men in committed gay relationships are fathering children through artificial insemination with surrogate mothers. Recent studies show that children raised in same sex couple households are not measurably different from children raised by heterosexual parents with respect to personality development, psychological development, and gender identity. These children are also not more likely to be gay or lesbian themselves.

Some single, never-married women who do not wish to marry but do want to become pregnant may do so through artificial or natural insemination. Such women constitute a group who believe that motherhood is the fulfillment of female identity, without which they view their lives to be incomplete. Most of these women have considered the consequence of single parenthood and feel able to rise to the challenges.

Sexual Behavior
The effects of pregnancy on sexual behavior vary. Some women experience an increased sex drive as pelvic vasocongestion produces a more sexually responsive state. Others are more responsive than before the pregnancy, because they no longer fear becoming pregnant. Some have diminished desire or lose interest in sexual activity altogether. Libido may be decreased because of higher estrogen levels or feelings of unattractiveness. Avoidance of sex may also result from physical discomfort or an association of motherhood with asexuality. Men with a madonna complex view pregnant women as sacred and not to be defiled by the sexual act. Either a man or a woman may erroneously consider intercourse potentially harmful to the developing fetus and, thus, something to be avoided. Men who have extramarital affairs during their wives’
pregnancies usually do so during the last trimester.

Coitus. Most obstetricians place no prohibitions on coitus during pregnancy. Some suggest that sexual intercourse cease 4 to 5 weeks antepartum. If bleeding occurs early in pregnancy, an obstetrician may prohibit coitus temporarily as a therapeutic measure. Bleeding in the first 20 days of pregnancy occurs in 20 to 25 percent of women and approximately half of that group experience spontaneous abortion. Maternal death resulting from forcibly blowing air into the vagina during cunnilingus has been reported; the deaths presumably result from air emboli in the placental–maternal circulation.

Parturition

Fears regarding pain and bodily harm during delivery are universal and, to some extent, warranted. Preparation for childbirth affords a sense of familiarity and can ease anxieties, which facilitates delivery. Continuous emotional support during labor reduces the rate of cesarean section and forceps deliveries, the need for anesthesia, the use of oxytocin (Pitocin), and the duration of labor. A technically difficult or even painful delivery, however, does not appear to influence the decision to bear additional children.

Men’s responses to pregnancy and labor have not been well studied, but the recent trend toward inclusion of fathers in the birth process eases their anxieties and elicits a fuller sense of participation. Fathers do not parent the same way as mothers, and new mothers sometimes need to be encouraged to respect these differences and view them positively.

Lamaze Method. Also known as natural childbirth, the Lamaze method originated with the French obstetrician Fernand Lamaze. In this method, women are fully conscious during labor and delivery, and no analgesic or anesthetic is used. The expectant mother and father attend special classes, during which they are taught relaxation and breathing exercises designed to facilitate the birth process. Women who have such training often report minimal pain during labor and delivery. Participating in the birth process may help a fearful or ambivalent father bond with his newborn infant.

Prenatal Screening

Prenatal screening for potential or actual fetal malformation is conducted in most pregnant women. Sonograms are noninvasive and can detect structural fetal abnormalities. Maternal α-fetoprotein (AFP) is measured between 15 and 20 weeks, screening for neural tube defects and Down syndrome. The sensitivity of Down syndrome testing is increased when a triple screen is done (AFP, hCG, and estriol). Amniocentesis is indicated for women over 35 years, those with a sibling or parent with a known chromosome anomaly, and those with abnormal AFP or any other risk for severe genetic disorder. Amniocentesis is usually done between 16 and 18 weeks and carries a risk that 1 in 300 women will miscarry after the procedure. In the first
trimester, chorionic villus sampling (CVS) can be done, which reveals the same information concerning chromosomal status, enzyme levels, and DNA (deoxyribonucleic acid) patterns. With CVS, there is a risk that 1 in 100 women will have a spontaneous abortion after the procedure.

Screening in the first trimester allows women to choose early termination, which may be physically and emotionally easier on the woman. Profound ethical questions are involved in whether or not to abort a fetus with a known defect. Some women choose not to terminate and report a strong loving bond that lasts throughout the life of the child, who usually predeceases the parent.

**Lactation**

Lactation occurs because of a complex psychoneuroendocrine cascade that is triggered by the abrupt decline in estrogen and progesterone concentrations at parturition. In general, babies should be fed as needed, rather than by schedule. Breast-feeding has many benefits. The composition of breast milk supports timely neuronal development, confers passive immunity, and reduces food allergies in the child. In subsistence-level cultures in which children are allowed to nurse as long as they want (a practice supported by La Leche League, a breast-feeding advocacy group), most babies will wean themselves between ages 3 and 5 if not encouraged by the mother to do so earlier. Women who decide to breast-feed need good teaching and social support, which if lacking may lead to frustration and feelings of inadequacy. Women must not feel pressured or coerced into breast-feeding if they are opposed or ambivalent. In the long term, no discernible difference exists between bottle-fed and breast-fed children as adults.

An incidental finding about lactation is that some women experience sexual sensations during lactation, which in rare cases can lead to orgasm. In the early 1990s a woman who called a help line about such feelings was put in jail and had her infant taken from her on allegations of sexual abuse. Common sense ultimately prevailed, however, and mother and infant were reunited.

**Perinatal Death**

Perinatal death, defined as death sometime between the 20th week of gestation and the first month of life, includes spontaneous abortion (miscarriage), fetal demise, stillbirth, and neonatal death. In previous years, the intense bond between the expectant or new parent and the fetus or neonate was underestimated, but perinatal loss is now recognized as a significant trauma for both parents. Parents who experience such a loss go through a period of mourning much as that experienced when any loved one is lost.

Intrauterine fetal death, which can occur at any time during the pregnancy, is an emotionally traumatic experience. In the early months of pregnancy, a woman is usually unaware of fetal death and learns of it only from her doctor. Later in pregnancy, after fetal movements and heart tones have been experienced, a woman may be able to detect fetal demise. When given the diagnosis of fetal death, most
women want the dead fetus removed; depending on the trimester, labor may be induced, or the woman may have to wait for spontaneous expulsion of the uterine contents. Many couples consider sexual relations during the period of waiting not only undesirable but psychologically unacceptable as well.

A sense of loss also accompanies the birth of a stillborn child and induced abortion of an abnormal fetus detected by antenatal diagnosis. As mentioned, attachment to an unborn child begins before birth, and grief and mourning occur after a loss at any time. The grief experienced after a third-trimester loss, however, is generally greater than that experienced after a first-trimester loss. Some parents do not wish to view a stillborn child, and their wishes should be respected. Others wish to hold the stillborn, and this act can assist the mourning process. A subsequent pregnancy may diminish overt feelings of grief, but it does not eliminate the need to mourn. So-called replacement children are at risk for overprotection and future emotional problems.

**CONCEPTION**

**Infertility**

Infertility is the inability of a couple to conceive after 1 year of coitus without the use of a contraceptive. In the United States, about 15 percent of married couples are unable to have children. In the past, women were blamed when couples did not have children, and feelings of guilt, depression, and inadequacy frequently accompanied the perception of being barren. Today, it is known that causes of infertility are attributed to disorders in men in 40 percent of cases, disorders in women in 40 percent, and disorders of both in 20 percent. Separate histories obtained for each partner (Table 27-1) and tests in an infertility workup (Table 27-2) usually reveal the specific cause; however, 10 to 20 percent of couples have no identifiable cause.

The inability to have a child can produce severe psychological stress on one or both partners in a marriage. Self-blame increases the likelihood of psychological problems. Women—but not men—are at increased risk for psychological distress if they are older and do not already have biological children. If one or both partners are unwilling to take advantage of assisted reproductive techniques, the marriage may falter. A psychiatric evaluation of the couple may be advisable. Marital disharmony or emotional conflicts about intimacy, sexual relations, or parenting roles can directly affect endocrine function and such physiological processes as erection, ejaculation, and ovulation. No evidence exists, however, for any simple, causal relation between stress and infertility.

When preexisting conflict gives rise to problems of identity, self-esteem, and guilt, the disturbance may be severe and may manifest through regression; extreme dependence on a physician, mate, or parent; diffuse anger; impulsive behavior; or depression. The problem is further complicated when hormone therapy is used to treat the infertility, because the therapy may temporarily increase depression in some patients. Mood and cognition can be altered by pharmacological agents used to treat disorders of ovulation or to hyperstimulate the ovaries.

Persons who have difficulty conceiving may experience shock, disbelief, and a general sense of helplessness, and they develop an understandable preoccupation with the problem. Involvement in the infertility workup and the development of expertise about infertility can be a constructive defense against feelings of inadequacy and the humiliating, sometimes painful aspects of the workup itself. Worries about attractiveness and sexual desirability are common. Partners may feel ugly or impotent, and episodes of sexual dysfunction and loss of desire are reported. These problems are aggravated when a couple is scheduling sexual relations according to temperature charts.

(Data are taken in part from Susman V. *Pregnancy in Behavioral Sciences for Medical Students.* Baltimore: Williams & Wilkins; 1993. Table by S. L. Berga, M.D., B. L. Parry, M.D., and E. E. Moses-Kolko, M.D.)

Single persons who are aware of their own infertility may shy away from relationships for fear of being rejected once their “defect” is known. Persons who are infertile may have particular difficulty in their adult relationships with their own parents. The identification and equality that come from sharing the experience of parenthood must be replaced by internal reserves and other generative aspects of their lives.

Professional intervention may be necessary to help infertile couples ventilate their feelings and go through the process of mourning for their lost biological functions and the children they cannot have. Couples who remain infertile must cope with an actual loss. Couples who decide not to pursue parenthood may develop a renewed sense of love, dedication, and identity as a pair. Others may need help in exploring the options of husband or donor insemination, laboratory implantation, and adoption.

**FAMILY PLANNING AND CONTRACEPTION**

Family planning is the process of choosing when, and if, to bear children. One form of family planning is contraception, the prevention of fecundation, or fertilization of the ovum. The choice of a contraceptive method (Table 27-4) is a complex decision involving both women and their partners. Factors influencing the decision include a
woman’s age and medical condition, her access to medical care, the couple’s religious beliefs, and the need for coital spontaneity. The woman and her partner can weigh the risks and benefits of the various forms of contraception and make their decision on the basis of their current lifestyle and other factors. The success of contraceptive technology has enabled career-minded couples to delay child-bearing into their 30s and 40s. Such a delay, however, may increase infertility problems. Consequently, many women with careers feel their biological clocks ticking and plan to have children while in their early 30s to avoid the risk of not being able to have them at all.

(Table by S. L. Berga, M.D., B. L. Parry, M.D., and E. L. Moses-Kolko, M.D.)
Sterilization

Sterilization is a procedure that prevents a man or a woman from producing offspring. In a woman, the procedure is usually salpingectomy, ligation of the fallopian tubes, a procedure with low morbidity and low mortality. A man is usually sterilized by vasectomy, excision of part of the vas deferens, which is a simpler procedure than salpingectomy and can be performed in a physician’s office. Voluntary sterilization, especially vasectomy, has become the most popular form of birth control in couples married for more than 10 years.

A small proportion of patients who elect sterilization may suffer from neurotic poststerilization syndrome, which can manifest through hypochondriasis, pain, loss of libido, sexual unresponsiveness, depression, and concerns about masculinity or femininity. One study of a group of women who regretted sterilization reported they had chosen the procedure while in poor relationships, frequently with abusive partners. Regret is most prevalent when a woman forms a new relationship and wishes to have a child with a new partner. Psychiatric consultation may be necessary to separate persons seeking sterilization for irrational or psychotic reasons from those who have made the decision after some time and thought.

The operative procedures for sterilization, namely vasectomy and tubal ligation, have assumed less importance than in the past because of the advent of contraceptives and the relative ease of obtaining abortions. Nonetheless, sterilization procedures are still chosen by men and women who, for a variety of reasons, want to permanently end their ability to produce children.

Abortion

Induced abortion is the planned termination of a pregnancy. About 1.3 million abortions are performed in the United States each year—246 abortions for every 1,000 live births. The various types of abortion are listed in Table 27-5. Over the past decade, the number of abortions has declined by about 15 percent. Family planning experts believe that more sex education and greater availability of contraceptive devices keep the number of abortions down. In Western countries, most women who obtain abortions are young, unmarried, and primiparous; in emerging countries, abortion is most common among married women with two or more children.

| Table 27-5 | Types of Abortion |
Of abortions, 60 percent are performed before 8 weeks of gestation, 88 percent are performed before 13 weeks, and 4.1 percent between 16 and 20 weeks, with 1.4 percent occurring after 21 weeks. **Table 27-6** summarizes the most common abortion techniques, and **Table 27-7** compares medical and surgical abortion techniques.

Abortion has become a political and philosophical issue in the United States. The country is sharply divided between pro-choice and pro-life factions. In recent years, antiabortion demonstrators have picketed abortion clinics and have provoked angry confrontations with patients. The atmosphere of moral condemnation and intimidation may make the decision to terminate a pregnancy difficult.

**Psychological Reactions to Abortion.** Recent studies demonstrate that most women who have an abortion for an unwanted pregnancy (i.e., induced abortion) were satisfied with their decision, with few, if any, negative psychological sequelae. Women who had miscarriages, however (i.e., spontaneous abortion), reported a high rate of dysphoric reactions. The difference can be explained, in part, by the fact that most women who induced abortion did so because they did not want the child. Women who spontaneously miscarried presumably wanted their babies. In the long term, however, about 10 percent of women who had induced abortion regretted having had the procedure.

Second-trimester abortions are more psychologically traumatic than first-trimester abortions. The most common reason for late abortions is the discovery (via amniocentesis or ultrasound) of an abnormal karyotype or fetal anomaly. Thus, late abortions usually involve the loss of a wanted child with whom the mother has already formed a bond.

Before the legalization of abortion in the United States in 1973, many women sought illegal abortions, often performed by untrained practitioners under nonsterile conditions. Considerable morbidity and mortality were associated with these abortions, and women who were denied abortion sometimes chose suicide over continuation of an unwanted pregnancy. In general, however, the risk of suicide is low in pregnant women, even in those who do not want a child but who carry the baby to term. When a woman is forced to carry a fetus to term, even though the risk of suicide is low, the risk increases for infanticide, abandonment, and neglect of the unwanted newborn.
Abortion can also be a significant experience for men. If a man has a close relationship with the woman, he may wish to play an active role in the abortion by accompanying her to the hospital or abortion clinic and providing emotional support. Fathers may experience considerable grief over the termination of a wanted pregnancy.

Reproductive Senescence
Both men and women age and experience an age-related decline in reproductive capacity, but only women experience complete gonadal cessation. Loss of reproductive capacity may present a psychological challenge to those who are not reconciled to the loss of fertility. Even with gonadal failure, however, the availability of donor oocytes and sperm means that pregnancy can be initiated in a menopausal woman with an intact uterus who elects to pursue that option. Studies have shown that older men may develop a genetic sperm mutation, giving rise to a higher incidence of autistic or schizophrenic offspring.

Menopause
Menopause, the cessation of ovulation, generally occurs between 47 and 53 years of age. The hypoestrogenism that follows can lead to hot flashes, sleep disturbances, vaginal atrophy and dryness, and cognitive and affective disturbances. Women are at increased risk for osteoporosis, dementia, and cardiovascular disease. Depression at menopause has been attributed to the “empty nest syndrome.” Many women, however, report an enhanced sense of well-being and enjoy opportunities to pursue goals postponed because of child rearing.

PSYCHIATRIC ASPECTS OF PREGNANCY
Postpartum Depression
Many women experience some affective symptoms during the postpartum period, 4 to 6 weeks following delivery. Most of these women report symptoms consistent with “baby blues,” a transient mood disturbance characterized by mood lability, sadness, dysphoria, subjective confusion, and tearfulness. These feelings, which may last several days, have been ascribed to rapid changes in women’s hormonal levels, the stress of childbirth, and the awareness of the increased responsibility that motherhood brings. No professional treatment is required other than education and support for the new mother. If the symptoms persist longer than 2 weeks, evaluation is indicated for postpartum depression.

Postpartum depression (coded as a subtype of major depressive disorder in the fifth edition of Diagnostic and Statistical Manual of Mental Disorders [DSM-5]) is characterized by a depressed mood, excessive anxiety, insomnia, and change in weight. The onset is generally within 12 weeks after delivery. No conclusive evidence indicates that “baby blues” will lead to a subsequent episode of depression. Several studies do indicate that
an episode of postpartum depression increases the risk of lifetime episodes of major depression. Treatment of postpartum depression is not well studied because of the risk of transmitting antidepressants to newborns during lactation. Table 27-8 differentiates postpartum “baby blues” from postpartum depression.

(From Miller L. How “baby blues” and postpartum depression differ. Women’s Psychiatric Health. 1995:13, with permission. Copyright 1995, The KSF Group.)

A syndrome described in fathers is characterized by mood changes during their wives’ pregnancies or after the babies are born. These fathers are affected by several factors: added responsibility, diminished sexual outlet, decreased attention from his wife, and the belief that the child is a binding force in an unsatisfactory marriage.

### Postpartum Psychosis
Postpartum psychosis (sometimes called *puerperal psychosis*) is an example of a psychotic disorder that occurs in women who have recently delivered a baby. The syndrome is often characterized by the mother’s depression, delusions, and thoughts of harming either herself or her infant. Such ideation of suicide or infanticide must be carefully monitored; although rare, some mothers have acted on these ideas. Most available data suggest a close relation between postpartum psychosis and mood disorders, particularly bipolar disorder and major depressive disorder. It is coded as a subtype of bipolar disorder in DSM-5.

The incidence of postpartum psychosis is about 1 to 2 per 1,000 childbirths. About 50 to 60 percent of affected women have just had their first child, and about 50 percent of cases involve deliveries associated with nonpsychiatric perinatal complications. About 50 percent of the affected women have a family history of mood disorders. The most robust data indicate that an episode of postpartum psychosis is essentially an episode of a mood disorder, usually a bipolar disorder but possibly a depressive disorder. Relatives of those with postpartum psychosis have an incidence of mood disorders that is similar
to the incidence in relatives of persons with mood disorders. As many as two thirds of the patients have a second episode of an underlying affective disorder during the year after a baby’s birth. The delivery process may best be seen as a nonspecific stress that causes the development of an episode of a major mood disorder, perhaps through a major hormonal mechanism.

The symptoms of postpartum psychosis can often begin within days of the delivery, although the mean time to onset is within 2 to 3 weeks and almost always within 8 weeks of delivery. Characteristically, patients begin to complain of fatigue, insomnia, and restlessness, and they may have episodes of tearfulness and emotional lability. Later, suspiciousness, confusion, incoherence, irrational statements, and obsessive concerns about the baby’s health and welfare may be present. Delusional material may involve the idea that the baby is dead or defective. Patients may deny the birth and express thoughts of being unmarried, virginal, persecuted, influenced, or perverse. Hallucinations with similar content may involve voices telling the patient to kill the baby or herself. Complaints regarding the inability to move, stand, or walk are also common.

The onset of florid psychotic symptoms is usually preceded by prodromal signs such as insomnia, restlessness, agitation, lability of mood, and mild cognitive deficits. Once the psychosis occurs, the patient may be a danger to herself or to her newborn, depending on the content of her delusional system and her degree of agitation. In one study, 5 percent of patients committed suicide and 4 percent committed infanticide. A favorable outcome is associated with a good premorbid adjustment and a supportive family network. Subsequent pregnancies are associated with an increased risk of another episode, sometimes as high as 50 percent.

As with any psychotic disorder, clinicians should consider the possibility of either a psychotic disorder caused by a general medical condition or a substance-induced psychotic disorder. Potential general medical conditions include hypothyroidism and Cushing’s syndrome. Substance-induced psychotic disorder can be associated with the use of pain medications such as pentazocine (Talwin) or of antihypertensive drugs during pregnancy. Other potential medical causes include infections, toxemia, and neoplasms.

Postpartum psychosis is a psychiatric emergency. Antipsychotic medications and lithium (Eskalith), often in combination with an antidepressant, are the treatments of choice. No pharmacological agents should be prescribed to a woman who is breast-feeding. Suicidal patients may require transfer to a psychiatric unit to help prevent a suicide attempt.

The mother is usually helped by contact with her baby if she so desires, but the visits must be closely supervised, especially if the mother is preoccupied with harming the infant. Psychotherapy is indicated after the period of acute psychosis, and therapy is usually directed at helping the patient accept and be at ease with the mothering role. Changes in environmental factors may also be indicated, such as increased support from the husband and others in the environment. Most studies report high rates of recovery from the acute illness.
Mrs. Z is a 30-year-old high school teacher living in Lagos, Nigeria. She is married and has five children. The birth of her last child was complicated by hemorrhage and sepsis, and she was still hospitalized on the gynecology service for 13 days after delivery when her gynecologist requested a psychiatric consultation. Mrs. Z was agitated and seemed to be in a daze. She said to the psychiatrist: “I am a sinner. I have to die. My time is past. I cannot be a good Christian again. I need to be reborn. Jesus Christ should help me. He is not helping me.” A diagnosis of postpartum psychosis was made. An antipsychotic drug, chlorpromazine (Thorazine), was prescribed, and Mrs. Z was soon well enough to go home. Three weeks later, she was readmitted, this time to the psychiatric ward, claiming she “had had a vision of the spirits” and was “wrestling with the spirits.” Her relatives reported that at home she had been fasting and “keeping a vigil” through the nights and was not sleeping. She had complained to the neighbors that there was a witch in her house. The witch turned out to be her mother. Mrs. Z’s husband, who was studying engineering in Europe, hurriedly returned and took over the running of the household, sending his mother-in-law away and supervising Mrs. Z’s treatment himself. She improved rapidly on an antidepressant medication and was discharged in 2 weeks. Her improvement, however, was short-lived. She threw away her medications and began to attend mass whenever one was given, pursuing the priests to ask questions about scriptures. Within 1 week, she was readmitted. On the ward, she accused the psychiatrist of shining powerful torchlights on her and taking pictures of her, opening her chest, using her as a guinea pig, poisoning her food, and planning to bury her alive. She claimed to receive messages from Mars and Jupiter and announced that there was a riot in town. She clutched her Bible to her breast and accused all the doctors of being “idol worshippers,” calling down the wrath of her god on all of them. After considerable resistance, Mrs. Z was finally convinced to accept electroconvulsive treatment, and she became symptom free after six treatments. At this point, she attributed her illness to a difficult childbirth, the absence of her husband, and her unreasonable mother. She saw no further role for doctors, called for her priest, and began to speak of her illness as a religious experience that was similar to the experience of religious leaders throughout history. However, her symptoms did not return, and she was discharged after 6 weeks of hospitalization. (Courtesy of Bushra Naz, M.D., Laura J. Fochtmann, M.D., and Evelyn J. Bromet, Ph.D.)

Psychotropic Medications in Pregnancy

No definitive answers exist to the questions of which psychotropic medications are safest during pregnancy and lactation. In patients with worsening psychiatric illness during pregnancy, outpatient psychotherapy, hospitalization, and milieu therapy should be attempted before routine use of psychotropic medication. The risks and benefits of treatment with psychotropics versus maternal psychiatric illness must be carefully evaluated on an individual basis. If the patient, her psychiatrist, and her obstetrician
decide to continue psychiatric medications throughout pregnancy, the dosage should be calibrated to the physiological changes each trimester. Although no antidepressant medications have been associated with intrauterine death or major birth defects, both selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs) are associated with a transient perinatal syndrome. Studies demonstrate that fluoxetine (Prozac) has been found in amniotic fluid. Mood stabilizers are associated with more consequential teratogenic risks, namely cardiac anomalies and neural tube defects, but women with bipolar disorder are at a significant risk of relapse without medication maintenance. Lithium has been associated with an increased risk of Ebstein’s anomaly, a congenital downward displacement of the tricuspid valve into the right ventricle.

The U.S. Food and Drug Administration (FDA) rates drugs in five categories of safety for use in pregnancy, with categories of risk coded A, B, C, D, and X (Table 27-9). In general, all medications that are not absolutely essential should be avoided during pregnancy.

### Teratogens

Teratogens are drugs or other agents that cause abnormal fetal development. Infections such as varicella, toxoplasmosis, and herpes simplex, among others, can interfere with normal development. Pregnant women who smoke are subject to premature births, and congenital defects are more common in smokers than in nonsmokers. Alcohol abuse is associated with fetal alcohol syndrome (see Section 20.2). Other drugs of abuse, such as cocaine and heroin, produce drug-dependent newborns. In general, pregnant women should not use prescription and over-the-counter drugs and phytomedicinals. Drugs given in the third trimester are rarely teratogenic. Retinoids (used to treat acne) taken early in pregnancy have been associated with fetal abnormalities.

### Premenstrual Dysphoric Disorder
Premenstrual dysphoric disorder (PMDD) is a somatopsychic illness triggered by changing levels of sex steroids that accompany an ovulatory menstrual cycle. It occurs about 1 week before the onset of menses and is characterized by irritability, emotional lability, headache, anxiety, and depression. Somatic symptoms include edema, weight gain, breast pain, syncope, and paresthesias. The diagnostic criteria for premenstrual dysphoric disorder according to DSM-5 are listed in Table 27-10. Approximately 5 percent of women have the disorder. Treatment is symptomatic and includes analgesics for pain and sedatives for anxiety and insomnia. Some patients respond to short courses of SSRIs. Fluid retention is relieved with diuretics.

| Table 27-10 |
| DSM-5 Criteria for Premenstrual Dysphoric Disorder |
The generally recognized syndrome involves mood symptoms (e.g., lability, irritability), behavior symptoms (e.g., changes in eating patterns, insomnia), and physical symptoms (e.g., breast tenderness, edema, and headaches). This pattern of symptoms occurs at a specific time during the menstrual cycle, and the symptoms resolve for some period of time between menstrual cycles. The hormonal changes that occur during the menstrual cycle are probably involved in producing the symptoms, although the exact etiology is unknown.

Because of the absence of generally agreed-upon diagnostic criteria, the epidemiology of premenstrual dysphoria is not known with certainty. Up to 80 percent of all women experience some alteration in mood, sleep, or somatic symptoms during the premenstrual period, and about 40 percent of these women have at least mild to
moderate premenstrual symptoms prompting them to seek medical advice. Only 3 to 7 percent of women have symptoms that meet the full diagnostic criteria for PMDD.

Given that most women who experience changes in affect or somatic symptoms during the premenstrual period are not severely functionally impaired, it is important to distinguish these women from those who are diagnosed with PMDD. Premenstrual syndrome (PMS) is distinguished from PMDD by the severity and number of symptoms, as well as the degree to which function is impaired. Table 27-11 lists the diagnostic criteria for PMS in which the patient reports at least one of the affective or somatic symptoms during the 5 days before menses in each of the three prior menstrual cycles.

</table>

Table 27-11 Diagnostic Criteria for Premenstrual Syndrome

(Adapted from American College of Obstetricians and Gynecologists [ACOG] Practice Bulletin #15, April 2000, with permission.)

The course and the prognosis of PMDD have not been studied sufficiently to reach any reasonable conclusions. Anecdotally, the symptoms tend to be chronic unless effective treatment is initiated. Treatment of PMDD includes support for the patient about the presence and recognition of the symptoms. SSRIs (e.g., fluoxetine) and alprazolam (Xanax) have been reported to be effective, although no treatment has been conclusively demonstrated to be effective in multiple, well-controlled trials. If symptoms are present throughout the menstrual cycle, with no intercycle symptom relief, clinicians should consider one of the nonmenstrual cycle–related mood disorders and anxiety disorders. The presence of especially severe symptoms, even if cyclical, should prompt clinicians to consider other mood disorders and anxiety disorders. A thorough medical workup is necessary to rule out medical or surgical conditions to account for symptoms (e.g., endometriosis).

OTHER ISSUES

Sexually Transmitted Diseases

A sexually transmitted disease (STD) is a contagious disease acquired as a result of a physical sexual interaction. From the 1950s through 1970s, the infections were considered treatable and not life-threatening. That was before acquired immune deficiency syndrome (AIDS) was recognized, which is caused by infection with human immunodeficiency virus (HIV) and is currently incurable, life-threatening, and transmissible from mother to fetus.

A sequela of STDs, such as gonorrhea and chlamydia, is pelvic inflammatory disease.
Untreated, PID can develop into bilateral tubo-ovarian abscesses and necessitate hysterectomy and bilateral salpingo-oophorectomy. Early antibiotic treatment is advocated to prevent development of the abscesses and to reduce the likelihood of infertility, chronic pelvic pain, and ectopic pregnancy from tubal damage. These infections also can lead to obstruction of the vas deferens and chronic prostatitis and subsequent male infertility.

Another STD that can have serious consequences is venereal warts, or human papillomavirus (HPV). Genital infections with certain subtypes of HPV can lead to premalignant changes of the penis, vulva, vagina, and cervix and are thought to cause cervical cancer. Venereal warts can be removed chemically or surgically but are difficult to eradicate completely. Women who contract HPV are encouraged to have regular gynecological examinations and Papanicolaou smears to detect premalignant lesions. An HPV vaccine exists, which is recommended for all girls 11 to 12 years of age to decrease the incidence of certain strains of HPV virus. This vaccine would then decrease the incidence of genital warts and cervical cancer.

Sexual monogamy and abstinence, which will prevent most STDs, are advocated as public health measures. Libidinal impulses, however, can be difficult to control and restrict. Therefore, measures such as condom use are strongly recommended as an alternative public health measure. Adolescents, in particular, need to know the potential consequences of sexual activity with regard to STDs and pregnancy. Admonishing teens to remain chaste is unlikely to be completely effective and may be counterproductive. The risks of sexual intercourse may be forgotten or seem minimal in comparison to the need for affection or escape. Persons with low self-esteem or under stress may view sex as a means of bolstering their self-image or escaping their stresses. The reinforcing properties of sex ensure that the problem of STDs will endure. Studies in Europe, especially Holland, have shown that easy availability of condoms (e.g., in schools) reduces both STDs and unwanted pregnancies.

Pelvic Pain
Pelvic pain can have many causes, including endometriosis, pelvic adhesions, ovarian or adnexal masses, hernias, and bowel or rectal disease. Pelvic pain can also be secondary to psychogenic causes such as guilt, fertility, or fears of infertility, and the emotional disturbances associated with ongoing or past incest or sexual abuse. Pelvic pain should not be attributed to psychogenic causes unless a thorough evaluation has excluded organic causes. In most instances, the evaluation should include a diagnostic laparoscopy. Likewise, dyspareunia or pain with intercourse should not be assumed to have a psychogenic origin unless all anatomical causes have been excluded.

Pseudocyesis
Pseudocyesis (false pregnancy) is the development of the classic symptoms of pregnancy—amenorrhea, nausea, breast enlargement and pigmentation, abdominal distention (Fig. 27-2), and labor pains—in a nonpregnant woman. Pseudocyesis demonstrates the
ability of the psyche to dominate the soma, probably via central input at the level of the hypothalamus. Predisposing psychological processes are thought to include a pathological wish for, and fear of, pregnancy; ambivalence or conflict regarding gender, sexuality, or childbearing; and a grief reaction to loss following a miscarriage, tubal ligation, or hysterectomy. The patient may have a true somatic delusion that is not subject to reality testing, but often a negative pregnancy test result or pelvic ultrasound scan leads to resolution. Psychotherapy is recommended during or after a presentation of pseudocyesis to evaluate and treat the underlying psychological dysfunction. A related event, couvade, occurs in some cultures in which the father of the child undergoes simulated labor, as though he were giving birth. In those societies couvade is a normal phenomenon.

**FIGURE 27-2** Abdominal distention in patient at 36th week. Bimanual examination revealed uterus normal in size and position.

Miss S, aged 16, thought she had become pregnant after her first coital experience, which occurred without contraception. Shortly after she read about the signs and symptoms of pregnancy, her menses stopped. She related that she felt tingling in her breasts, which she believed were enlarged. She also reported nausea and vomiting in the morning, which was observed by her mother. On examination, the uterus was enlarged, breasts were developed with dark areola and contained milk, and a pigmented line was observed from the umbilicus to the pubis. The abdomen was not enlarged, but she believed she felt fetal movement. A pregnancy test had negative results and the patient was so informed; however, she could not be dissuaded of her belief that she was pregnant. She entered psychotherapy, and within 2 months her menses returned and she accepted the fact that she was not pregnant.
Hyperemesis Gravidarum

Hyperemesis gravidarum is differentiated from morning sickness in that vomiting is chronic, persistent, and frequent, leading to ketosis, acidosis, weight loss, and dehydration. The prognosis is excellent for both mother and fetus with prompt treatment. Most women can be treated as outpatients, with changing to smaller meals, discontinuing iron supplements, and avoiding certain foods. In severe cases, hospitalization may be necessary. Although the cause is unknown, a psychological component may exist. Women with histories of anorexia nervosa or bulimia nervosa may be at risk.

Pica

Pica is the repeated ingestion of nonnutritive substances, such as dirt, clay, starch, sand, and feces. This eating disorder is most often seen in young children, but is common in pregnant women in some subcultures, most notably among African American women in the rural South, who may eat clay or starch (e.g., Argo). The cause of pica is unknown, but it may be related to nutritional deficiencies in the mother.

28.1 Psychoanalysis and Psychoanalytic Psychotherapy

As broadly practiced today, psychoanalytic treatment encompasses a wide range of uncovering strategies used in varied degrees and blends. Despite the inevitable blurring of boundaries in actual application, the original modality of classic psychoanalysis and major modes of psychoanalytic psychotherapy (expressive and supportive) are delineated separately here (Table 28.1-1). Analytical practice in all its complexity resides on a continuum. Individual technique is always a matter of emphasis, as the therapist titrates the treatment according to the needs and capacities of the patient at every moment.

Table 28.1-1
Scope of Psychoanalytic Practice: A Clinical Continuum
Psychoanalysis is virtually synonymous with the renowned name of its founding father, Sigmund Freud (Freud and his theories are discussed in Section 4.1). It is also referred to as “classic” or “orthodox” psychoanalysis to distinguish it from more recent variations known as psychoanalytic psychotherapy (discussed below).

Psychoanalysis is based on the theory of sexual repression and traces the unfulfilled infantile libidinal wishes in the individual’s unconscious memories. It remains unsurpassed as a method to discover the meaning and motivation of behavior, especially the unconscious elements that inform thoughts and feelings.
PSYCHOANALYSIS

Psychoanalytic Process

The psychoanalytic process involves bringing to the surface repressed memories and feelings by means of a scrupulous unraveling of hidden meanings of verbalized material and of the unwitting ways in which the patient wards off underlying conflicts through defensive forgetting and repetition of the past.

The overall process of analysis is one in which unconscious neurotic conflicts are recovered from memory and verbally expressed, reexperienced in the transference, reconstructed by the analyst, and, ultimately, resolved through understanding. Freud referred to these processes as recollection, repetition, and working through, which make up the totality of remembering, reliving, and gaining insight. Recollection entails the extension of memory back to early childhood events, a time in the distant past when the core of neurosis was formed. The actual reconstruction of these events comes through reminiscence, associations, and autobiographical linking of developmental events. Repetition involves more than mere mental recall; it is an emotional replay of former interactions with significant individuals in the patient’s life. The replay occurs within the special context of the analyst as projected parent, a fantasized object from the patient’s past with whom the latter unwittingly reproduces forgotten, unresolved feelings and experiences from childhood. Finally, working through is both an affective and cognitive integration of previously repressed memories that have been brought into consciousness and through which the patient is gradually set free (cured of neurosis). The analytical course can be subdivided into three major stages (Table 28.1-2).

Table 28.1-2
Stages of Psychoanalysis
Indications and Contraindications

In general, all of the so-called psychoneuroses are suitable for psychoanalysis. These include anxiety disorders, obsessional thinking, compulsive behavior, conversion disorder, sexual dysfunction, depressive states, and many other nonpsychotic conditions, such as personality disorders. Significant suffering must be present so that patients are motivated to make the sacrifices of time and financial resources required for psychoanalysis. Patients who enter analysis must have a genuine wish to understand themselves, not a desperate hunger for symptomatic relief. They must be able to withstand frustration, anxiety, and other strong affects that emerge in analysis without fleeing or acting out their feelings in a self-destructive manner. They must also have a reasonable, mature superego that allows them to be honest with the analyst. Intelligence must be at least average, and above all, they must be psychologically minded in the sense that they can think abstractly and symbolically about the unconscious meanings of their behavior.

Many contraindications for psychoanalysis are the flip side of the indications. The absence of suffering, poor impulse control, inability to tolerate frustration and anxiety, and low motivation to understand are all contraindications. The presence of extreme dishonesty or antisocial personality disorder contraindicates analytic treatment. Concrete thinking or the absence of psychological mindedness is another contraindication. Some patients who might ordinarily be psychologically minded are not suitable for analysis because they are in the midst of a major upheaval or life crisis, such as a job loss or a divorce. Serious physical illness can also interfere with a person’s ability to invest in a long-term treatment process. Patients of low intelligence generally
do not understand the procedure or cooperate in the process. An age older than 40 years was once considered a contraindication, but today analysts recognize that patients are malleable and analyzable in their 60s or 70s. One final contraindication is a close relationship with the analyst. Analysts should avoid analyzing friends, relatives, or persons with whom they have other involvements.

Patient Requisites

The most important patient requisites for psychoanalysis are listed in Table 28.1-3.

Table 28.1-3
Patient Prerequisites for Psychoanalysis

1. High motivation. The patient needs a strong motivation to persevere, in light of the rigors of intense and lengthy treatment. The desire for health and self-understanding must surpass the neurotic need for unhappiness. The patient must be willing to face issues of time and money and to endure the pain and frustration associated with sacrificing rapid relief in favor of future cure and with foregoing the secondary gains of illness.

2. Ability to form a relationship. The capacity to form and maintain, as well as to detach from, a trusting object relationship is essential. The patient also has to withstand a frustrating and regressive transference without decompensating or becoming excessively attached. Patients with a history of impaired or transient interpersonal relations who cannot establish a viable connection to another human make poor candidates for psychoanalysis.

3. Psychological mindedness and capacity for insight. As an introspective process, psychoanalysis requires curiosity about oneself and the capacity for self-scrutiny. Those who are unable to articulate and comprehend their inner thoughts and feelings cannot negotiate with the fundamental analytical coin words and their meanings. The inability to examine one's own motivations and behaviors precludes benefits from the analytical method.

4. Ego strength. Ego strength is the integrative capacity to oscillate appropriately between two antithetical types of ego functioning: On the one hand, the patient must be able to reflect temporarily, to relinquish reality for fantasy, and to be dependent and passive. On the other hand, the patient has to be able to accept analytical rules, to integrate interpretations, to defer important decisions, to shift perspectives to become an observer of his or her intrapsychic processes, and to function in a sustained interpersonal relationship as a responsible adult.

Ms. M, a 29-year-old unmarried woman who worked in a low-level capacity for a magazine, presented for consultation with the chief complaints of considerable sadness and distress over her parent’s reaction when they found that she had had a homosexual relationship. She also realized that she had been working far below her potential. She had never sought any treatment before. She was clearly intelligent, sensitive, self-reflective, and insightful. When the possibility of psychoanalysis was presented to her, she worried that meant she was “sicker.” Ms. M, however, began reading Freud, realized that analysis was actually recommended for those who are higher functioning, and became intrigued by the idea. She agreed to come 4 days a
She was the oldest of three children and the only girl. Ms. M’s father, a successful professional, was described as very demanding and intrusive, someone who never thought anything was good enough. He had always expected his children to do the “extra credit” assignments as part of their regular work. Ms. M, however, was very proud of her father’s accomplishments. She spoke of her mother in conflicting terms as well: She was a homemaker, weak, and sometimes acquiescent to the powerful father but also a woman in her own right who was involved in community volunteer work and could be a powerful public speaker.

Just prior to beginning her analysis, Ms. M had had her wallet stolen. In her first analytic session, she spoke of losing all of her identification cards, and to her it seemed as if she were starting analysis “with a completely new identity.” Initially, she was somewhat hesitant to use the couch because she wanted to see her analyst’s reactions, but she quickly appreciated that she could associate more easily without seeing the analyst.

As her analysis proceeded, through dreams and free associations, Ms. M became quite focused on the analyst. She became extremely curious about the analyst’s life. What emerged from her associations to seeing the analyst’s appointment book on the desk was that she felt “slotted in.” Whenever Ms. M saw other patients, she felt the office was “like an assembly line.” Further associations led to her feeling slotted in by her parents as they ran from one activity to another. Her resistance manifested itself in Ms. M’s often coming as much or more than 15 minutes late to her sessions. Her associations led to her admitting that she did not want her analyst to think that she was “too eager.” Ms. M was able to see that she needed to devalue her analyst and her importance to Ms. M as a defense against an overwhelming positive and even erotic transference toward her.

For example, Ms. M wanted to improve her appearance so that the therapist, who she called a “role model,” would find her more attractive. Her negative transference, however, was never far from the surface, and she denigrated the analyst by wondering if the analyst were a “clotheshorse” who was financing her wardrobe with the patient’s payments.

Her conflicts about her sexual orientation were a central preoccupation in the course of her analysis, particularly because her father was so homophobic. Early on, Ms. M felt awkward and uncomfortable when she went to a lesbian bar, and when asked if she qualified for the “lesbian discount,” she said she did not. At one point, she began seeing several men, including a male psychologist. The analyst made the transference interpretation, which Ms. M accepted, that a date with this man seemed as if it were a date with the analyst and sleeping with him would be equivalent to sleeping with the analyst. Ms. M was also able to see that her transient choice of dating a male therapist was a defensive compromise. Although her homosexual object choice was multidetermined, Ms. M came to appreciate, through her work in analysis, that at least a part of her conflicts about homosexuality stemmed from her relationship toward her father. It was a means of securing his attention as well as
infuriating him.

Over the course of 4 years, Ms. M began to do considerably better at work and was promoted to a job commensurate with her potential. She was also able to deal better with both her parents, and particularly her father, regarding her sexual orientation. She became much more comfortable with her “new identity” and became involved in a relationship with a professional woman. At the end of therapy, Ms. M and this woman were committed to each other and were thinking of adopting a child. (Courtesy of T. Byram Karasu, M.D., and S. R. Karasu, M.D.)

Goals
Stated in developmental terms, psychoanalysis aims at the gradual removal of amnesias rooted in early childhood based on the assumption that when all gaps in memory have been filled, the morbid condition will cease because the patient no longer needs to repeat or remain fixated to the past. The patient should be better able to relinquish former regressive patterns and to develop new, more adaptive ones, particularly as he or she learns the reasons for his or her behavior. A related goal of psychoanalysis is for the patient to achieve some measure of self-understanding or insight.

Psychoanalytic goals are often considered formidable (e.g., a total personality change), involving the radical reorganization of old developmental patterns based on earlier affects and the entrenched defenses built up against them. Goals may also be elusive, framed as they are in theoretical intrapsychic terms (e.g., greater ego strength) or conceptually ambiguous ones (resolution of the transference neurosis). Criteria for successful psychoanalysis may be largely intangible and subjective and they are best regarded as conceptual endpoints of treatment that must be translated into more realistic and practical terms.

In practice, the goals of psychoanalysis for any patient naturally vary, as do the many manifestations of neuroses. The form that the neurosis takes—unsatisfactory sexual or object relationships, inability to enjoy life, underachievement, and fear of work or academic success, or excessive anxiety, guilt, or depressive ideation—determines the focus of attention and the general direction of treatment, as well as the specific goals. Such goals may change at any time during the course of analysis, especially as many years of treatment may be involved.

Major Approach and Techniques
Structurally, psychoanalysis usually refers to individual (dyadic) treatment that is frequent (four or five times per week) and long term (several years). All three features take their precedent from Freud himself.

The dyadic arrangement is a direct function of the Freudian theory of neurosis as an intrapsychic phenomenon, which takes place within the person as instinctual impulses continually seek discharge. Because dynamic conflicts must be internally resolved if structural personality reorganization is to take place, the individual’s memory and
perceptions of the repressed past are pivotal. Freud initially saw patients 6 days a week for 1 hour each day, a routine now reduced to four or five sessions per week of the classic 50-minute hour, which leaves time for the analyst to take notes and organize relevant thoughts before the next patient. Long intervals between sessions are avoided so that the momentum gained in uncovering conflictual material is not lost and confronted defenses do not have time to restrengthen.

Freud’s belief that successful psychoanalysis always takes a long time because profound changes in the mind occur slowly still holds. The process can be likened to the fluid sense of time that is characteristic of our unconscious processes. Moreover, because psychoanalysis involves a detailed recapitulation of present and past events, any compromise in time presents the risk of losing pace with the patient’s mental life.

Psychoanalytic Setting. As with other forms of psychotherapy, psychoanalysis takes place in a professional setting, apart from the realities of everyday life, in which the patient is offered a temporary sanctuary in which to ease psychic pain and reveal intimate thoughts to an accepting expert. The psychoanalytic environment is designed to promote relaxation and regression. The setting is usually spartan and sensorially neutral, and external stimuli are minimized.

USE OF THE COUCH. The couch has several clinical advantages that are both real and symbolic: (1) the reclining position is relaxing because it is associated with sleep and so eases the patient’s conscious control of thoughts; (2) it minimizes the intrusive influence of the analyst, thus curbing unnecessary cues; (3) it permits the analyst to make observations of the patient without interruption; and (4) it holds symbolic value for both parties, a tangible reminder of the Freudian legacy that gives credibility to the analyst’s professional identity, allegiance, and expertise. The reclining position of the patient with analyst nearby can also generate threat and discomfort, however, as it recalls anxieties derived from the earlier parent–child configuration that it physically resembles. It may also have personal meanings—for some, a portent of dangerous impulses or of submission to an authority figure; for others, a relief from confrontation by the analyst (e.g., fear of use of the couch and overeagerness to lie down may reflect resistance and, thus, need to be analyzed). Although the use of the couch is requisite to analytical technique, it is not applied automatically; it is introduced gradually and can be suspended whenever additional regression is unnecessary or counter-therapeutic.

FUNDAMENTAL RULE. The fundamental rule of free association requires patients to tell the analyst everything that comes into their heads—however disagreeable, unimportant, or nonsensical—and to let themselves go as they would in a conversation that leads from “cabbages to kings.” It differs decidedly from ordinary conversation—instead of connecting personal remarks with a rational thread, the patient is asked to reveal those very thoughts and events that are objectionable precisely because of being averse to doing so.

This directive represents an ideal because free association does not arise freely but is
guided and inhibited by a variety of conscious and unconscious forces. The analyst must not only encourage free association through the physical setting and a nonjudgmental attitude toward the patient’s verbalizations, but also examine those very instances when the flow of associations is diminished or comes to a halt—they are as important analytically as the content of the associations. The analyst should also be alert to how individual patients use or misuse the fundamental rule.

Aside from its primary purpose of eliciting recall of deeply hidden early memories, the fundamental rule reflects the analytical priority placed on verbalization, which translates the patient’s thoughts into words so they are not channeled physically or behaviorally. As a direct concomitant of the fundamental rule, which prohibits action in favor of verbal expression, patients are expected to postpone making major alterations in their lives, such as marrying or changing careers, until they discuss and analyze them within the context of treatment.

PRINCIPLE OF EVENLY SUSPENDED ATTENTION. As a reciprocal corollary to the rule that patients communicate everything that occurs to them without criticism or selection, the principle of evenly suspended attention requires the analyst to suspend judgment and to give impartial attention to every detail equally. The method consists simply of making no effort to concentrate on anything specific, while maintaining a neutral, quiet attentiveness to all that is said.

ANALYST AS MIRROR. A second principle is the recommendation that the analyst be impenetrable to the patient and, as a mirror, reflect only what is shown. Analysts are advised to be neutral blank screens and not to bring their own personalities into treatment. This means that they are not to bring their own values or attitudes into the discussion or to share personal reactions or mutual conflicts with their patients, although they may sometimes be tempted to do so. The bringing in of reality and external influences can interrupt or bias the patient’s unconscious projections. Neutrality also allows the analyst to accept without censure all forbidden or objectionable responses.

RULE OF ABSTINENCE. The fundamental rule of abstinence does not mean corporal or sexual abstinence, but refers to the frustration of emotional needs and wishes that the patient may have toward the analyst or part of the transference. It allows the patient’s longings to persist and serve as driving forces for analytical work and motivation to change. Freud advised that the analyst carry through the analytical treatment in a state of renunciation. The analyst must deny the patient who is longing for love the satisfaction he or she craves.

Limitations. At present, the predominant treatment constraints are often economic, relating to the high cost in time and money, both for patients and in the training of future practitioners. In addition, because clinical requirements emphasize such requisites as psychological mindedness, verbal and cognitive ability, and stable life situation, psychoanalysis may be unduly restricted to a diagnostically, socioeconomically, or
Ms. A, a 25-year-old articulate and introspective medical student, began analysis complaining of mild, chronic anxiety, dysphoria, and a sense of inadequacy, despite above-average intelligence and performance. She also expressed difficulty in long-term relationships with her male peers.

Ms. A began the initial phase of analysis with enthusiastic self-disclosure, frequent reports of dreams and fantasies, and overidealization of the analyst; she tried to please him by being a compliant, good patient, just as she had been a good daughter to her father (a professor of medicine) by going to medical school.

Over the next several months, Ms. A gradually developed a strong attachment to the analyst and settled into a phase of excessive preoccupation with him. Simultaneously, however, she began dating an older psychiatrist and proceeded to complain about the analyst’s coldness and unresponsiveness, even considering dropping out of analysis because he did not meet her demands.

In the course of analysis, through dreams and associations, Ms. A recalled early memories of her ongoing competition with her mother for her father’s attention and realized that, failing to obtain his exclusive love, she had tried to become like him. She was also able to see how her increasing interest in becoming a psychiatrist (rather than following her original plan to be a pediatrician), as well as her recent choice of a man to date, were recapitulations of the past vis-à-vis the analyst. As this repeated pattern was recognized, the patient began to relinquish her intense erotic and dependent tie to the analyst, viewing him more realistically and beginning to appreciate the ways in which his quiet presence reminded her of her mother. She also became less disturbed by the similarities she shared with her mother and was able to disengage from her father more comfortably. By the fifth year of analysis, she was happily married to a classmate, was pregnant, and was a pediatric chief resident. Her anxiety was now attenuated and situation specific (that is, she was concerned about motherhood and the termination of analysis). (Courtesy of T. Byram Karasu, M.D.)

PSYCHOANALYTIC PSYCHOTHERAPY

Psychoanalytic psychotherapy, which is based on fundamental dynamic formulations and techniques that derive from psychoanalysis, is designed to broaden its scope. Psychoanalytic psychotherapy, in its narrowest sense, is the use of insight-oriented
As generically applied today to an ever-larger clinical spectrum, it incorporates a blend of uncovering and suppressive measures.

The strategies of psychoanalytic psychotherapy currently range from expressive (insight-oriented, uncovering, evocative, or interpretive) techniques to supportive (relationship-oriented, suggestive, suppressive, or repressive) techniques. Although those two types of methods are sometimes regarded as antithetical, their precise definitions and the distinctions between them are by no means absolute.

The duration of psychoanalytic psychotherapy is generally shorter and more variable than in psychoanalysis. Treatment may be brief, even with an initially agreed-upon or fixed time limit, or may extend to a less definite number of months or years. Brief treatment is chiefly used for selected problems or highly focused conflict, whereas longer treatment may be applied for more chronic conditions or for intermittent episodes that require ongoing attention to deal with pervasive conflict or recurrent decompensation. Unlike psychoanalysis, psychoanalytic psychotherapy rarely uses the couch; instead, patient and therapist sit face to face. This posture helps to prevent regression because it encourages the patient to look on the therapist as a real person from whom to receive direct cues, even though transference and fantasy will continue. The couch is considered unnecessary because the free-association method is rarely used, except when the therapist wishes to gain access to fantasy material or dreams to enlighten a particular issue.

**Expressive Psychotherapy**

**Indications and Contraindications.** Diagnostically, psychoanalytic psychotherapy in its expressive mode is suited to a range of psychopathology with mild to moderate ego weakening, including neurotic conflicts, symptom complexes, reactive conditions, and the whole realm of nonpsychotic character disorders, including those disorders of the self that are among the more transient and less profound on the severity-of-illness spectrum, such as narcissistic behavior disorders and narcissistic personality disorders. It is also one of the treatments recommended for patients with borderline personality disorders, although special variations may be required to deal with the associated turbulent personality characteristics, primitive defense mechanisms, tendencies toward regressive episodes, and irrational attachments to the analyst.

Ms. B, an intelligent and verbal 34-year-old divorced woman, presented with complaints of being unappreciated at work. Always angry and irritable, she considered quitting her job and even leaving the city. Her social life was also being negatively affected; her boyfriend had threatened to leave her because of her extremely hostile, clinging behavior (the same reason her ex-husband had given when he left her 9 years earlier after only 16 months of marriage).

Her past included promiscuity and experimentation with various drugs, and, currently, she indulged in heavy drinking on weekends and occasionally smoked
marijuana. She had held many jobs and had lived in various cities. The eldest of three children of a middle-class family, she came from an unhappy and unstable home: her brother had been in and out of psychiatric hospitals; her sister had left home at the age of 16 after becoming pregnant and being forced to marry; and her overly controlling parents had subjected their children to psychological (and occasionally physical) abuse, alternating between heated arguments and passionate reconciliations.

Initially, Ms. B attempted to contain her rage in treatment, but it frequently surfaced and alternated with child-like helplessness; she interrogated the psychiatrist regarding his credentials, ridiculed psychodynamic concepts, constantly challenged statements, and would demand practical advice but then denigrate or fail to follow the guidance given. The psychiatrist remained unprovoked by her aggression and explored with her the need to engage him negatively. Her response was to question and test his continued concern.

When her boyfriend left her, she attempted suicide (she cut her wrists superficially), was briefly hospitalized, and, on discharge, was placed on selective serotonin reuptake inhibitors (SSRIs) for 6 months for her minor, but protracted, depression. The psychiatrist maintained their regular frequency of sessions despite her greater demands. Although she was puzzled by the steadiness of his interest, she gradually felt safe enough to express her vulnerabilities. As they explored her lack of full commitment to work, friends, and therapy, she began to understand the meaning of her anger in terms of the early abusive relationship with her parents and her tendency to bring it into contemporary relationships. With the psychiatrist’s encouragement, she also began to seek work and make small strides in relationship-oriented efforts. By the end of her second year of treatment, she had decided to remain in the city, to stay at her place of employment, and to continue therapy. She needed to experience and practice her somewhat fragile new self, which included greater intimacy in relationships, additional mastery of work skills, and a more cohesive sense of self. (Courtesy of T. Byram Karasu, M.D.)

The persons best suited for the expressive psychotherapy approach have fairly well integrated egos and the capacity to both sustain and detach from a bond of dependency and trust. They are, to some degree, psychologically minded and self-motivated, and they are generally able, at least temporarily, to tolerate doses of frustration without decompensating. They must also have the ability to manage the arousal of painful feelings outside the therapy hour without additional contact. Patients must have some capacity for introspection and impulse control, and they should be able to recognize the cognitive distinction between fantasy and reality.

Goals. The overall goals of expressive psychotherapy are to increase the patient’s self-awareness and to improve object relations through exploration of current interpersonal events and perceptions. In contrast to psychoanalysis, major structural
changes in ego function and defenses are modified in light of patient limitations. The aim is to achieve a more limited and, thus, select and focused understanding of one’s problems. Rather than uncovering deeply hidden and past motives and tracing them back to their origins in infancy, the major thrust is to deal with preconscious or conscious derivatives of conflicts as they became manifest in present interactions. Although insight is sought, it is less extensive; instead of delving to a genetic level, greater emphasis is on clarifying recent dynamic patterns and maladaptive behaviors in the present.

**Major Approach and Techniques.** The major modus operandi involves establishment of a therapeutic alliance and early recognition and interpretation of negative transference. Only limited or controlled regression is encouraged, and positive transference manifestations are generally left unexplored, unless they are impeding therapeutic progress; even here, the emphasis is on shedding light on current dynamic patterns and defenses.

**Limitations.** A general limitation of expressive psychotherapy, as of psychoanalysis, is the problem of emotional integration of cognitive awareness. The major danger for patients who are at the more disorganized end of the diagnostic spectrum, however, may have less to do with the overintellectualization that is sometimes seen in neurotic patients than with the threat of decompensation from, or acting out of, deep or frequent interpretations that the patient is unable to integrate properly.

Some therapists fail to accept the limitations of a modified insight-oriented approach and so apply it inappropriately to modulate the techniques and goals of psychoanalysis. Overemphasis on dreams and fantasies, zealous efforts to use the couch, indiscriminate deep interpretations, and continual focus on the analysis of transference may have less to do with the patient’s needs than with those of a therapist who is unwilling or unable to be flexible.

Ms. S was an attractive 30-year-old unmarried woman working as a secretary when she presented for consultation. Her chief complaints at the time were feeling “only anger and tension” and an inability to apply herself to studying voice, “which is one of the most important things to me.”

In obtaining a history, the therapist noted that Ms. S had never completed anything: She had dropped out of college; never pursued a music degree; and switched from job to job, and even city to city. What initially seemed like a woman with diverse interests (e.g., jobs as a research assistant, freelance copyeditor, part-time radio announcer; manager of data entry for a software company; and, most recently, secretary) really reflected a woman with a chaotic lifestyle and serious difficulties committing to anyone or anything. Although obviously intelligent, Ms. S presented with unrealistic expectations regarding her consultation. For example, after the first
consultative session, Ms. S said she felt good afterward but felt there were “no revelations yet.” Because of Ms. S’s inability to commit and her somewhat disorganized life, the therapist recommended a course of psychotherapy, beginning twice a week, rather than something more intense like psychoanalysis. The therapist also realized over the course of the consultation that Ms. S would have difficulty with free association without getting disorganized. The therapist also thought that Ms. S might regress unproductively on the couch without visual contact with the therapist.

Ms. S was the second oldest of four children—two brothers and a younger sister, with whom she was most competitive and who clearly seemed the mother’s favorite. She described her mother as a successful professor who was demanding and critical, as if she had a “raised eyebrow” in disapproval. For example, much to her mother’s chagrin, Ms. S had once wanted a sandwich “with everything on it.” Ms. S was also disappointed when she was given one piece of luggage rather than a complete set for a Christmas gift. She was able to accept the therapist’s interpretation that she felt “part of a set” by being one of four siblings. Ms. S initially idealized her father, who was active in the family church, but eventually saw him as disappointing and rejecting.

Ms. S’s ideal therapist would be “flexible,” by which she meant a therapist who might do hypnosis one session, psychotherapy the next, and, maybe, analysis another session. In fact, within the first week of beginning therapy, Ms. S had simultaneously consulted a hypnotherapist, which she mentioned in passing only weeks later, for her neck pain and tension. Although she did not pursue hypnosis, she did maintain a chiropractor for most of her therapy, also something she mentioned many months after beginning therapy. She did speak of wanting to be “on best behavior” and “follow the rules.” Her tremendous sense of entitlement, however, was evident: She had an expectation of getting “cut-rate prices” on everything from haircuts and car repairs to doctors’ visits. Her initial fee was a much-reduced one, which she paid late and begrudgingly.

Although she was seen only twice a week, Ms. S developed intense feelings for her therapist. Mostly she experienced rage when she saw evidence of the therapist’s other patients, such as footprints on the waiting room floor after a snowstorm or a coat hanger turned around. She expressed the wish to keep some of her things, like bobby pins and hairspray, in the therapist’s bathroom. She vacillated between feelings she wanted to move in and feelings that the therapist did not exist. For example, before she took a plane flight, she wondered who would tell her therapist if something happened to her. She had never given the therapist’s name to anyone, nor did she have her name in her weekly appointment book. The therapist interpreted that she had a simultaneous wish to devalue her and not to share her with anyone else. Associations to a dream with an image of a string of baroque pearls led to thoughts that these pearls—irregular and imperfect—defective and even lopsided, represented how she viewed herself.

Over the course of the next few years, Ms. S was able to commit to coming regularly to therapy, although the course was somewhat tumultuous, with many threats of
Supportive Psychotherapy

Supportive psychotherapy aims at the creation of a therapeutic relationship as a temporary buttress or bridge for the deficient patient. It has roots in virtually every therapy that recognizes the ameliorative effects of emotional support and a stable, caring atmosphere in the management of patients. As a nonspecific attitude toward mental illness, it predates scientific psychiatry, with foundations in 18th-century moral treatment, whereby for the first time patients were treated with understanding and kindness in a humane, interpersonal environment free from mechanical restraints.

Supportive psychotherapy has been the chief form used in the general practice of medicine and rehabilitation, frequently to augment extratherapeutic measures, such as prescriptions of medication to suppress symptoms, rest to remove the patient from excessive stimulation, or hospitalization to provide a structured therapeutic environment, protection, and control of the patient. It can be applied as primary or ancillary treatment. The global perspective of supportive psychotherapy (often part of a combined treatment approach) places major etiological emphasis on external rather than intrapsychic events, particularly on stressful environmental and interpersonal influences on a severely damaged self.

Indications and Contraindications. Supportive psychotherapy is generally indicated for those patients for whom classic psychoanalysis or insight-oriented psychoanalytic psychotherapy is typically contraindicated—those who have poor ego strength and whose potential for decompensation is high. Amenable patients fall into the following major areas: (1) individuals in acute crisis or a temporary state of disorganization and inability to cope (including those who might otherwise be well functioning) whose intolerable life circumstances have produced extreme anxiety or
sudden turmoil (e.g., individuals going through grief reactions, illness, divorce, job loss, or who were victims of crime, abuse, natural disaster, or accident); (2) patients with chronic severe pathology with fragile or deficient ego functioning (e.g., those with latent psychosis, impulse disorder, or severe character disturbance); (3) patients whose cognitive deficits and physical symptoms make them particularly vulnerable and, thus, unsuitable for an insight-oriented approach (e.g., certain psychosomatic or medically ill persons); and (4) individuals who are psychologically unmotivated, although not necessarily characterologically resistant to a depth approach (e.g., patients who come to treatment in response to family or agency pressure and are interested only in immediate relief or those who need assistance in very specific problem areas of social adjustment as a possible prelude to more exploratory work).

Mr. C, a 50-year-old married man with two sons, the owner of a small construction company, was referred by his internist after recovery from bypass surgery because of frequent, unfounded physical complaints. He was taking minor tranquilizers in increasing doses, not complying with his daily regimen, avoiding sexual contact with his wife, and had dropped out of group therapy for postsurgical patients after one session.

He came to his first appointment 20 minutes late, after having “forgotten” two previous appointments. He was extremely anxious, often lost in his train of thought, and was semidelusional about his wife and sons, suggesting that they might want to have him locked up. He briefly told his life history, which included his coming from a strict and hard-working but caring middle-class family and the death of his mother when he was only 11 years old. He had joined his father’s business (taking over after his father’s death 2 years earlier), with both of his sons as associates. Describing himself as successful in work and marriage, he claimed that “the only test I ever failed was the stress test.”

Mr. C explained his lack of compliance with diet restrictions as a lack of will and his constant contact with the internist as his having real physical problems not yet diagnosed; he rejected the idea of addiction to tranquilizers, insisting that he could quit any time. He had no fantasy life, remembered no dreams, made it clear that he had entered treatment on his internist’s instruction only, and started each session by stating that he had nothing to talk about.

After suggesting that Mr. C was coming to sessions just to pass the “sanity test” and that there was no reason to have him locked up, the psychiatrist encouraged the patient to join him in figuring out the real reasons for his anxiety. Initial sessions were devoted to discussing the patient’s medical condition and providing factual information about heart and bypass surgery. The therapist likened the patient’s condition to that of an older house getting new plumbing, trying to allay his unrealistic fears of impending death. As Mr. C’s anxiety declined, he became less defensive and more psychologically accessible. As the therapist began to explore his difficulty in accepting help, Mr. C was able to talk about his inability to admit
problems (i.e., weaknesses). The therapist's explicit recognition of the patient's strength in admitting his weaknesses encouraged the patient to reveal more about himself—how he had welcomed his father's death and his belief that perhaps his illness was punishment. The psychiatrist also encouraged him to speak about his unrealistic guilt and, at the same time, helped him recognize his suspicion of his sons as the reflection of his own wishes concerning his father and his lack of commitment to his medical regimen as a wish to die so as to expiate guilt. After steady urging by the therapist, Mr. C returned to work. He agreed to meet monthly with the psychiatrist and to taper off his use of tranquilizers. He even agreed that he might see the psychiatrist for “deep analysis” in the future because his wife now jokingly complained of his obsessive dieting, his uncompromising exercise regimens, and his regularly scheduled sexual activities. (Courtesy of T. Byram Karasu, M.D.)

Because support forms a tacit part of every therapeutic modality, it is rarely contraindicated as such. The typical attitude regards better-functioning patients as unsuitable not because they will be harmed by a supportive approach, but because they will not be sufficiently benefited by it. In aiming to maximize the patient’s potential for further growth and change, supportive therapy tends to be regarded as relatively restricted and superficial and, thus, is not recommended as the treatment of choice if the patient is available for, and capable of, a more in-depth approach.

Goals. The general aim of supportive treatment is the amelioration or relief of symptoms through behavioral or environmental restructuring within the existing psychic framework. This often means helping the patient to adapt better to problems and to live more comfortably with his or her psychopathology. To restore the disorganized, fragile, or decompensated patient to a state of relative equilibrium, the major goal is to suppress or control symptomatology and to stabilize the patient in a protective and reassuring benign atmosphere that militates against overwhelming external and internal pressures. The ultimate goal is to maximize the integrative or adaptive capacities so that the patient increases the ability to cope, while decreasing vulnerability by reinforcing assets and strengthening defenses.

Major Approach and Techniques. Supportive therapy uses several methods, either singly or in combination, including warm, friendly, strong leadership; partial gratification of dependency needs; support in the ultimate development of legitimate independence; help in developing pleasurable activities (e.g., hobbies); adequate rest and diversion; removal of excessive strain, when possible; hospitalization, when indicated; medication to alleviate symptoms; and guidance and advice in dealing with current issues. This therapy uses techniques to help patients feel secure, accepted, protected, encouraged, safe, and not anxious.

Limitations. To the extent that much supportive therapy is spent on practical, everyday realities and on dealing with the external environment of the patient, it may
be viewed as more mundane and superficial than depth approaches. Because those patients are seen intermittently and less frequently, the interpersonal commitment may not be as compelling on the part of either the patient or the therapist. Greater severity of illness (and possible psychoses) also makes such treatment potentially more erratic, demanding, and frustrating. The need for the therapist to deal with other family members, caretakers, or agencies (auxiliary treatment, hospitalization) can become an additional complication, because the therapist comes to serve as an ombudsman to negotiate with the outside world of the patient and with other professional peers. Finally, the supportive therapist must be able to accept personal limitations and the patient’s limited psychological resources and to tolerate the often unrewarded efforts until small gains are made.

Mr. W was a 42-year-old widowed businessman who was referred by his internist because of the sudden death of his wife, who had had an intracranial hemorrhage, about 2 months earlier. Mr. W had two children, a boy and a girl, ages 10 and 8 years, respectively.

Mr. W had never been to a psychiatrist before, and when he arrived he admitted he was not certain what a psychiatrist could do for him. He just had to get over his wife’s death. He was not sure how talking about anything could really help. He had been married for 15 years. He admitted to having difficulty sleeping, particularly awakening in the middle of the night with considerable anxiety about the future. One of his relatives had given him some of her own Klonopin for his anxiety, which helped tremendously, but he feared getting dependent on it. He was also drinking more than he thought he should. He was most concerned about raising his children alone and felt somewhat overwhelmed by the responsibility. He was beginning to appreciate just how wonderful a mother his wife had been and now saw how critical he had been of her for spending so much time with the children. “It really does take a lot of effort,” he said.

Mr. W did admit to feelings of guilt. For one thing, he admitted to some sense that he could now start over. He had been somewhat restless in the marriage recently before his wife’s death and had actually been unfaithful for a brief period early in the marriage. He also felt some guilt that had he been awake the night of his wife’s hemorrhage, maybe he could have saved his wife. In reality, there was nothing he could have done.

Mr. W agreed to come for a few sessions to talk about his wife. At this point, only 2 months after her death, he seemed to have an uncomplicated mourning reaction. Although he talked easily in session, he was clearly worried that he might like “being here too much.” The therapist chose not to interpret his dependency conflicts. Mr. W seemed to have good coping skills and used humor as a high-functioning defense. For example, in giving a eulogy for his wife (who had been a very popular member of their congregation), he looked around at the enormous crowd of people at the church service and said he had never seen so many people attending church before, adding,
“Sorry, Reverend.”

After about four sessions, Mr. W said he that felt better and no longer saw the need for further sessions. He was sleeping better and had stopped drinking excessively. The therapist suggested that he might want to continue to talk more about his guilt and his life as he went forward without his wife. The therapist was also reassuring that there seemed to be nothing else Mr. W could have done to save his wife. He also encouraged the patient to begin dating when he felt ready, something that Mr. W’s in-laws were clearly not encouraging. For now, however, Mr. W was not interested in any further therapy. He was appreciative of the therapist and felt that talking about his wife’s death had been helpful. The therapist accepted his wish to discontinue their sessions but encouraged Mr. W to keep in touch to let him know how he was doing. (Courtesy of T. Byram Karasu, M.D., and S. R. Karasu, M.D.)

CORRECTIVE EMOTIONAL EXPERIENCE. The relationship between therapist and patient gives a therapist an opportunity to display behavior different from the destructive or unproductive behavior of a patient’s parent. At times, such experiences seem to neutralize or reverse some effects of the parents’ mistakes. If the patient had overly authoritarian parents, the therapist’s friendly, flexible, nonjudgmental, nonauthoritarian—but at times firm and limit setting—attitude gives the patient an opportunity to adjust to, be led by, and identify with a new parent figure. Franz Alexander described this process as a corrective emotional experience. It draws on elements of both psychoanalysis and psychoanalytic psychotherapy.

28.2 Brief Psychodynamic Psychotherapy

The growth of psychotherapy in general and of dynamic psychotherapies derived from the psychoanalytic framework in particular represents a landmark achievement in the history of psychiatry. Brief psychodynamic psychotherapy has gained widespread popularity, partly because of the great pressure on health care professionals to contain treatment costs. It is also easier to evaluate treatment efficacy by comparing groups of persons who have had short-term therapy for mental illness with control groups than it is to measure the results of long-term psychotherapy. Thus, short-term therapies have been the subject of much research, especially on outcome measures, which have found them to be effective. Other short-term methods include interpersonal therapy (discussed in Section 28.10) and cognitive-behavioral therapy (discussed in Section 28.7).

Brief psychodynamic psychotherapy is a time-limited treatment (10 to 12 sessions) that is based on psychoanalysis and psychodynamic theory. It is used to help persons with depression, anxiety, and posttraumatic stress disorder, among others. There are several methods, each having its own treatment technique and specific criteria for selecting patients; however, they are more similar than different.

In 1946, Franz Alexander and Thomas French identified the basic characteristics of brief psychodynamic psychotherapy. They described a therapeutic experience designed to put patients at ease, to manipulate the transference, and to use trial interpretations flexibly. Alexander and French conceived psychotherapy as a corrective emotional experience capable of repairing traumatic events of the past and convincing patients that new ways of thinking, feeling, and behaving are possible. At about the same time, Eric Lindemann established a consultation service at Massachusetts General Hospital in Boston for persons experiencing a crisis. He developed new treatment methods to deal with these situations and eventually applied these techniques to persons who were not in crisis, but who were experiencing various kinds of emotional distress. Since then, the field has been influenced by many workers such as David Malan in England, Peter Sifneos in the United States, and Habib Davanloo in Canada.

**TYPES**

**Brief Focal Psychotherapy (Tavistock–Malan)**

Brief focal psychotherapy was originally developed in the 1950s by the Balint team at the Tavistock Clinic in London. Malan, a member of the team, reported the results of the therapy. Malan’s selection criteria for treatment included eliminating absolute
contraindications, rejecting patients for whom certain dangers seemed inevitable, clearly assessing patients’ psychopathology, and determining patients’ capacities to consider problems in emotional terms, face disturbing material, respond to interpretations, and endure the stress of the treatment. Malan found that high motivation invariably correlated with a successful outcome. Contraindications to treatment were serious suicide attempts, substance dependence, chronic alcohol abuse, incapacitating chronic obsessional symptoms, incapacitating chronic phobic symptoms, and gross destructive or self-destructive acting out.

Requirements and Techniques. In Malan’s routine, therapists should identify the transference early and interpret it and the negative transference. They should then link the transferences to patients’ relationships with their parents. Both patients and therapists should be willing to become deeply involved and to bear the ensuing tension. Therapists should formulate a circumscribed focus and set a termination date in advance, and patients should work through grief and anger about termination. An experienced therapist should allow about 20 sessions as an average length for the therapy; a trainee should allow about 30 sessions. Malan himself did not exceed 40 interviews with his patients.

Time-Limited Psychotherapy (Boston University–Mann)

A psychotherapeutic model of exactly 12 interviews focusing on a specified central issue was developed at Boston University by James Mann and his colleagues in the early 1970s. In contrast with Malan’s emphasis on clear-cut selection and rejection criteria, Mann has not been as explicit about the appropriate candidates for time-limited psychotherapy. Mann considered the major emphases of his theory to be determining a patient’s central conflict reasonably correctly and exploring young persons’ maturational crises with many psychological and somatic complaints. Mann’s exceptions, similar to his rejection criteria, include persons with major depressive disorder that interferes with the treatment agreement, those with acute psychotic states, and desperate patients who need, but cannot tolerate, object relations.

Requirements and Techniques. Mann’s technical requirements included strict limitation to 12 sessions, positive transference predominating early, specification and strict adherence to a central issue involving transference, positive identification, making separation a maturational event for patients, absolute prospect of termination to avoid development of dependence, clarification of present and past experiences and resistances, active therapists who support and encourage patients, and education of patients through direct information, reeducation, and manipulation. The conflicts likely to be encountered included independence versus dependence, activity versus passivity, unresolved or delayed grief, and adequate versus inadequate self-esteem.

Short-Term Dynamic Psychotherapy (McGill University–Davanloo)
As conducted by Davanloo at McGill University, short-term dynamic psychotherapy encompasses nearly all varieties of brief psychotherapy and crisis intervention. Patients treated in Davanloo’s series are classified as those whose psychological conflicts are predominantly oedipal, those whose conflicts are not oedipal, and those whose conflicts have more than one focus. Davanloo also devised a specific psychotherapeutic technique for patients with severe, long-standing neurotic problems, specifically those with incapacitating obsessive-compulsive disorders and phobias.

Davanloo’s selection criteria emphasize evaluating those ego functions of primary importance to psychotherapeutic work: the establishment of a psychotherapeutic focus; the psychodynamic formulation of the patient’s psychological problems; the ability to interact emotionally with evaluators; a history of give-and-take relationships with a significant person in the patient’s life; the patient’s ability to experience and tolerate anxiety, guilt, and depression; the patient’s motivations for change, psychological mindedness, and an ability to respond to interpretation and to link evaluators with persons in the present and past. Both Malan and Davanloo emphasized a patient’s responses to interpretation as an important selection and prognostic criterion.

Requirements and Techniques. The highlights of Davanloo’s psychotherapeutic approach are flexibility (therapists should adapt the technique to the patient’s needs), control, the patient’s regressive tendencies, active intervention to avoid having the patient develop overdependence on a therapist, and the patient’s intellectual insight and emotional experiences in the transference. These emotional experiences become corrective as a result of the interpretation.

Ana, a divorced 60-year-old woman, sought psychiatric help following a severe depressive episode lasting several months. This episode, which was one of many in her life, was especially severe in terms of loss of energy, interest, and motivation, as well as in terms of the intensity of her sadness and her wish to die. Only her profound religious convictions protected her from acting on these wishes. Ana had lost a lot of weight, had trouble sleeping, experienced many nightmares, and had difficulty with concentration. She was plagued by pervasive feelings of hatred for her mother, who was very old, ill, and dependent on Ana, who was unable to forgive her for abandoning her in an orphanage when she was 5 or 6 years of age.

After an extensive assessment, the dynamic formulation of Ana’s problem was represented as follows:

1. **Life problems**: Recurrent depressive episodes plagued by feelings of guilt and self-reproach; problems with men involving choosing partners who are commonly cold, distant, or otherwise unavailable; involuntary and painful emotional distance from her children, friends, and other close relationships; and unproductive and unrewarding work life, despite considerable intellectual gifts.

2. **Dynamics**: Ambivalent relationship with her mother, whom she blames for most of the tragedies of her life; guilt and need for punishment in relation to her unrelenting
hatred for her mother; and pathological grief reaction for the loss of an idealized and more optimal relationship with her mother, the one she remembers she had prior to her orphanage placement. From this focus there flows a melancholic conviction of the inevitable failure of human relationships.

3. **Pathogenic foci:** Grief and inability to mourn the loss of her mother after she was placed in the orphanage, with attendant rage and guilt; pathological grief for the loss of her father, who, because of severe alcoholism, abandoned the family first, a move that caused the mother to place her children in an orphanage in order to be able to work and ultimately recover their care. Unconsciously, she blamed her mother for the family catastrophe, thus “protecting” an idealized view of her father, to whom she was profoundly attached.

For Ana, the initial phase of treatment focused on the clarification and the experience of her destructive impulses toward her mother, which, as they were worked through, made possible the appearance of a modicum of empathy with her mother’s painful life situation around the time she placed Ana and her sisters in the orphanage. Next, the therapy focused on Ana’s father. Deep feelings of idealization, disappointment, anger, and grief were experienced with increasing clarity and intensity, frequently via displaced feelings in the transference and after overcoming considerable resistance. The last phase of treatment permitted the development of realistic feelings of empathy and appreciation for her mother, now without anger or emotional distancing, and the reawakening within Ana of feelings of joy and hope, as well as professional ambition. (Courtesy of M. Trujillo, M.D.)

**Short-Term Anxiety-Provoking Psychotherapy (Harvard University–Sifneos)**

Sifneos developed short-term anxiety-provoking psychotherapy at the Massachusetts General Hospital in Boston during the 1950s. He used the following criteria for selection: a circumscribed chief complaint (implying a patient’s ability to select one of a variety of problems to be given top priority and the patient’s desire to resolve the problem in treatment), one meaningful or give-and-take relationship during early childhood, the ability to interact flexibly with an evaluator and to express feelings appropriately, above-average psychological sophistication (implying not only above-average intelligence but also an ability to respond to interpretations), a specific psychodynamic formulation (usually a set of psychological conflicts underlying a patient’s difficulties and centering on an oedipal focus), a contract between therapist and patient to work on the specified focus and the formulation of minimal expectations of outcome, and good to excellent motivation for change, not just for symptom relief.

Chris, a 31-year-old single man, sought help for a moderate depressive episode precipitated by the loss of his relationship with his girlfriend, Joanna. She had broken
off the relationship after approximately 1 year, tired of Chris’s erratic work ethic and emotional instability and discouraged by his fear of commitment to the future of their relationship. This cycle of infatuation, increasing fear of commitment, and relationship loss had become a pattern in Chris’s interpersonal life. His work life was plagued with similar problems. Jobs were frequently lost because of serious conflict and threatening confrontations with his superiors. As conflicts arose at both work and home, Chris typically suffered increasing anxiety and episodic panic attacks. After the loss of each relationship, Chris usually confronted moderate depressive feelings, at times accompanied by suicidal ideation.

After an assessment, the dynamic hologram for Chris was represented as follows:

1. **Life problems:** Recurrent episodes of anxiety and depression; work problems; unstable interpersonal relationships; conflict with authority figures; antagonism toward, and emotional distance from, his father, brother, and male friends; and fears of heterosexual intimacy and of commitment.

2. **Dynamic forces:** Ongoing hostility and envy toward males, authority figures, and successful people, and compulsive and possessive seeking of female love objects with a serious inability to consider, fulfill, or tolerate their independent needs.

3. **Genetic pathogenic foci:** Unconscious loss of maternal objects precipitated by birth of a brother when Chris was age 2 years; uncontrolled grief for that loss with a compulsive drive to experience child-like possession of love objects; and compulsive hostility toward others perceived as rivals.

The therapist’s active inquiry yielded additional confirmation of the persistence of repressed sexual feelings toward his mother and the presence of hostile feelings toward all rivals for his mother’s affection. A memory suffused with very visceral feelings emerged in this phase as a result of the therapist’s active inquiry. In this memory, Chris saw himself in his mother’s arms in a dark room. He remembered vividly the intense pleasure of the contact with the warm skin of his mother, the texture of her clothes, and the smell of her perfume. While narrating this memory to the therapist, Chris was so absorbed in the experience that he blushed intensely. He also described the painful termination of this moment of pleasure by his father’s sudden and disruptive opening of the door and the flood of light that disturbed his pleasurable absorption. This sequence gave way to the experience of grief at the loss of the intense and exclusive bond with his mother after his brother’s birth and to a reexperiencing of a sense of anger, impotence, and loneliness. These feelings were all too familiar in his present life when his romantic attachments would be threatened or lost. The affective link between this childhood experience and his intimacy problems in the present became very obvious to Chris, and the acceptance of this link enhanced his capacity to work through this essential component of his pathology. A parallel conflict appeared in the transference as the patient resented the “intrusion” of the inquiring therapist into the zealously guarded privacy of this primal fantasy of material possession. (Courtesy of M. Trujillo, M.D.)
Requirements and Techniques. Treatment can be divided into four major phases: patient–therapist encounter, early therapy, height of treatment, and evidence of change and termination. Therapists use the following techniques during the four phases.

PATIENT–THERAPIST ENCOUNTER. A therapist establishes a working alliance by using the patient’s quick rapport with, and positive feelings for, the therapist that appear in this phase. Judicious use of open-ended and forced-choice questions enables the therapist to outline and concentrate on a therapeutic focus. The therapist specifies the minimal expectations of outcome to be achieved by the therapy.

EARLY THERAPY. In transference, feelings for the therapist are clarified as soon as they appear, a technique that leads to the establishment of a true therapeutic alliance.

HEIGHT OF THE TREATMENT. Height of treatment emphasizes active concentration on the oedipal conflicts that have been chosen as the therapeutic focus; repeated use of anxiety-provoking questions and confrontations; avoidance of pregenital characterological issues, which the patient uses defensively to avoid dealing with the therapist’s anxiety-provoking techniques; avoidance at all costs of a transference neurosis; repetitive demonstration of the patient’s neurotic ways or maladaptive patterns of behavior; concentration on the anxiety-laden material, even before the defense mechanisms have been clarified; repeated demonstrations of parent-transference links by the use of properly timed interpretations based on material given by the patient; establishment of a corrective emotional experience; encouragement and support of the patient, who becomes anxious while struggling to understand the conflicts; new learning and problem-solving patterns; and repeated presentations and recapitulations of the patient’s psychodynamics until the defense mechanisms used in dealing with oedipal conflicts are understood.

EVIDENCE OF CHANGE AND TERMINATION OF PSYCHOTHERAPY. The final phase of therapy emphasizes the tangible demonstration of change in the patient’s behavior outside therapy, evidence that adaptive patterns of behavior are being used, and initiation of talk about terminating the treatment.

OVERVIEW AND RESULTS

The shared techniques of all the brief psychotherapies described above outdistance their differences. They share the therapeutic alliance or dynamic interaction between therapist and patient, the use of transference, the active interpretation of a therapeutic focus or central issue, the repetitive links between parental and transference issues, and the early termination of therapy.

The outcomes of these brief treatments have been investigated extensively. Contrary to prevailing ideas that the therapeutic factors in psychotherapy are nonspecific, controlled studies and other assessment methods (e.g., interviews with unbiased evaluators, patients’ self-evaluations) point to the importance of the specific techniques used. The capacity for genuine recovery in certain patients is far greater than was
thought. A certain type of patient receiving brief psychotherapy can benefit greatly from a practical working through of his or her nuclear conflict in the transference. Such patients can be recognized in advance through a process of dynamic interaction, because they are responsive, motivated, and able to face disturbing feelings and because a circumscribed focus can be formulated for them. The more radical the technique in terms of transference, depth of interpretation, and the link to childhood, the more radical the therapeutic effects will be. For some disturbed patients, a carefully chosen partial focus can be therapeutically effective.

REFERENCES
Group psychotherapy is a modality that employs a professionally trained leader who selects, composes, organizes, and leads a collection of members to work together toward the maximal attainment of the goals for each individual in the group and for the group itself. Certain properties present in groups, such as mutual support, can be harnessed in the service of providing relief from psychological suffering and supply peer support to counter isolation experienced by many who seek psychiatric help. Similarly, homogeneously composed small groups are ideal settings for the dissemination of accurate information about a condition shared by group members. Medical illness, substance abuse, and chronic and persistent severe psychiatric conditions, including schizophrenia and major affective disorders, are cases in point.

A widely accepted psychiatric treatment modality, group psychotherapy uses therapeutic forces within the group, constructive interactions among members, and interventions of a trained leader to change the maladaptive behaviors, thoughts, and feelings of emotionally distressed individuals. In an era of increasingly stringent financial constraints, decreasing emphasis on individual psychotherapies, and expanding use of psychopharmacological approaches, more patients have been treated with group psychotherapy than with any other form of verbal therapy. Group therapy is applicable to inpatient and outpatient settings, institutional work, partial hospitalization units, halfway houses, community settings, and private practice. Group psychotherapy is also widely used by those who are not mental health professionals in the adjuvant treatment of physical disorders. The principles of group psychotherapy have also been applied with success in the fields of business and education in the form of training, sensitivity, and role-playing.

Group psychotherapy is a treatment in which carefully selected persons who are emotionally ill meet in a group guided by a trained therapist and help one another effect personality change. By using a variety of technical maneuvers and theoretical constructs, the leader directs group members’ interactions to bring about changes.

CLASSIFICATION

Group therapy at present has many approaches. Some clinicians work within a psychoanalytic frame of reference. Others use therapy techniques, such as transactional group therapy, which was devised by Eric Berne and emphasizes the here-and-now interactions among group members; behavioral group therapy, which relies on conditioning techniques based on learning theory; Gestalt group therapy, which was created from the theories of Frederick Perls, enables patients to abreact and express themselves fully; and client-centered group psychotherapy, which was developed by Carl Rogers and is based on the nonjudgmental expression of feelings among group members. Table 28.3-1 outlines the major group psychotherapy approaches.

PATIENT SELECTION

To determine a patient’s suitability for group psychotherapy, a therapist needs a great deal of information, which is gathered in a screening interview. The psychiatrist should take a psychiatric history and perform a mental status examination to obtain certain dynamic, behavioral, and diagnostic information. Table 28.3-2 outlines the general criteria for the selection of patients for group therapy.

**Authority Anxiety**

Those patients whose primary problem is their relationship to authority and who are extremely anxious in the presence of authority figures may do well in group therapy because they are more comfortable in a group and more likely to do better in a group than in a dyadic (one-to-one) setting. Patients with a great deal of authority anxiety may be blocked, anxious, resistant, and unwilling to verbalize thoughts and feelings in an individual setting, generally for fear of the therapist’s censure or disapproval. Thus, they may welcome the suggestion of group psychotherapy to avoid the scrutiny of the dyadic situation. Conversely, if a patient reacts negatively to the suggestion of group psychotherapy or openly resists the idea, the therapist should consider the possibility that the patient has high peer anxiety.

**Peer Anxiety**

Patients with conditions such as borderline and schizoid personality disorders who have destructive relationships with their peer groups or who have been extremely isolated from peer group contact generally react negatively or anxiously when placed in a group setting. When such patients can work through their anxiety, however, group therapy can be beneficial.

Robert entered therapy seeking to understand why he was unable to maintain close or lasting relationships. A handsome and successful businessman, he had made a painful and courageous transition away from self-centered, dysfunctional parents early in his life. Although he made good initial impressions in his jobs, he was always puzzled and disappointed when his superiors gradually lost interest in him and his colleagues avoided him. In one-on-one therapy, he was charming and entertaining, but was easily injured by perceived narcissistic slights and would become angry and attacking. Group psychotherapy was suggested when his transference feelings remained intense and therapy was at a seeming impasse. Initially, Robert charmed the group and strove to be the center of attention. Visibly annoyed whenever he felt the group leader was paying more attention to other members, Robert was especially critical and hostile toward older people in the group and displayed little empathy for others. After repeated and forceful confrontations from the group about his
antagonistic behavior, he gradually realized that he was repeating childhood patterns in his family of desperately seeking the attention of unloving parents and then entering violent rages when they lost interest. (Courtesy of Normund Wong, M.D.)

Diagnosis
The diagnosis of patients’ disorders is important in determining the best therapeutic approach and in evaluating patients’ motivations for treatment, capacities for change, and personality structure strengths and weaknesses. Few contraindications exist to group therapy. Antisocial patients generally do poorly in a heterogeneous group setting because they cannot adhere to group standards; but if the group is composed of other antisocial patients, they may respond better to peers than to perceived authority figures. Depressed patients profit from group therapy after they have established a trusting relationship with the therapist. Patients who are actively suicidal or severely depressed should not be treated solely in a group setting. Patients who are manic are disruptive but, once under pharmacological control, do well in the group setting. Patients who are delusional and who may incorporate the group into their delusional system should be excluded, as should patients who pose a physical threat to other members because of uncontrollable aggressive outbursts.

PREPARATION
Patients prepared by a therapist for a group experience tend to continue in treatment longer and report less initial anxiety than those who are not prepared. The preparation consists of having a therapist explain the procedure in as much detail as possible and answer the patient’s questions before the first session.

STRUCTURAL ORGANIZATION
Table 28.3-2 summarizes some of the critical tasks that a group therapist must face when organizing a group.

Size
Group therapy has been successful with as few as 3 members and as many as 15, but most therapists consider 8 to 10 members the optimal size. Interaction may be insufficient with fewer members unless they are especially verbal, and with more than 10 members, the interaction may be too great for the members or the therapist to follow.

Frequency and Length of Sessions
Most group psychotherapists conduct group sessions once a week. Maintaining continuity in sessions is important. When there are alternate sessions, the group meets
twice a week, once with and once without the therapist. Group sessions generally last anywhere from 1 to 2 hours, but the time limit should be constant.

Marathon groups were most popular in the 1970s but are much less common today. In time-extended therapy (marathon group therapy), the group meets continuously for 12 to 72 hours. Enforced interactional proximity and, during the longest time-extended sessions, sleep deprivation break down certain ego defenses, release affective processes, and theoretically promote open communication. Time-extended sessions, however, can be dangerous for patients with weak ego structures, such as persons with schizophrenia or borderline personality disorder.

Homogeneous versus Heterogeneous Groups
Most therapists believe that groups should be as heterogeneous as possible to ensure maximal interaction. Members with different diagnostic categories and varied behavioral patterns; from all races, social levels, and educational backgrounds; and of varying ages and both sexes should be brought together. Patients between the ages of 20 and 65 years can be included effectively in the same group. Age differences help in developing parent–child and brother–sister models, and patients have the opportunity to relive and rectify interpersonal difficulties that may have appeared insurmountable.

Both children and adolescents are best treated in groups comprising mostly persons in their own age groups. Some adolescent patients are capable of assimilating the material of an adult group, regardless of content, but they should not be deprived of a constructive peer experience that they might otherwise not have.

Open versus Closed Groups
Closed groups have a set number and composition of patients. If members leave, no new members are accepted. In open groups, membership is more fluid, and new members are taken on whenever old members leave.

MECHANISMS
Group Formation
Each patient approaches group therapy differently and, in this sense, groups are microcosms. Patients use typical adaptive abilities, defense mechanisms, and ways of relating, and when these tactics are ultimately reflected back to them by the group, they learn to be introspective about their personality functioning. A process inherent in group formation requires that patients suspend their previous ways of coping. In entering the group, they allow their executive ego functions—reality testing, adaptation to and mastery of the environment, and perception—to be assumed, to some degree, by the collective assessment provided by the total membership, including the leader.

Therapeutic Factors
Table 28.3-3 outlines 20 significant therapeutic factors that account for change in group psychotherapy.

### Table 28.3-3
**Twenty Therapeutic Factors in Group Psychotherapy**

<table>
<thead>
<tr>
<th>Factor</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Abreaction</td>
<td>A process by which repressed material, particularly a painful experience or conflict, is brought back to consciousness. In the process, the person not only recalls but relieves the material, which is accompanied by the appropriate emotional response; insight usually results from the experience.</td>
</tr>
<tr>
<td>Acceptance</td>
<td>The feeling of being accepted by other members of the group; differences of opinion are tolerated, and there is an absence of censure.</td>
</tr>
<tr>
<td>Altruism</td>
<td>The act of one member helping another; putting another person's need before one's own and learning that there is value in giving to others. The term was originated by Auguste Comte (1798–1857), and Sigmund Freud believed it was a major factor in establishing group cohesion and community feeling.</td>
</tr>
<tr>
<td>Catharsis</td>
<td>The expression of ideas, thoughts, and suppressed material that is accompanied by an emotional response that produces a state of relief in the patient.</td>
</tr>
<tr>
<td>Cohesion</td>
<td>The sense that the group is working together toward a common goal; also referred to as a sense of &quot;we-ness&quot;; believed to be the most important factor related to positive therapeutic effects.</td>
</tr>
<tr>
<td>Consensual validation</td>
<td>Confirmation of reality by comparing one's own conceptualizations with those of other group members; interpersonal distortions are thereby corrected. The term was introduced by Harry Stack Sullivan; Trigant Burrow had used the phrase &quot;consensual observation&quot; to refer to the same phenomenon.</td>
</tr>
<tr>
<td>Contagion</td>
<td>The process in which the expression of emotion by one member stimulates the awareness of a similar emotion in another member.</td>
</tr>
<tr>
<td>Corrective familial experience</td>
<td>The group re-creates the family of origin for some members who can work through original conflicts psychologically through group interaction (e.g., sibling rivalry, anger toward parents).</td>
</tr>
<tr>
<td>Empathy</td>
<td>The capacity of a group member to put himself or herself into the psychological frame of reference of another group member and thereby understand his or her thinking, feeling, or behavior.</td>
</tr>
<tr>
<td>Identification</td>
<td>An unconscious defense mechanism in which the person incorporates the characteristics and the qualities of another person or object into his or her ego system.</td>
</tr>
<tr>
<td>Imitation</td>
<td>The conscious emulation or modeling of one's behavior after that of another (also called role modeling); also known as spectator therapy, as one patient learns from another.</td>
</tr>
<tr>
<td>Insight</td>
<td>Conscious awareness and understanding of one's own psychodynamics and symptoms of maladaptive behavior. Most therapists distinguish two types: (1) intellectual insight—knowledge and awareness without any changes in maladaptive behavior; (2) emotional insight—awareness and understanding leading to positive changes in personality and behavior.</td>
</tr>
<tr>
<td>Inspiration</td>
<td>The process of imparting a sense of optimism to group members; the ability to recognize that one has the capacity to overcome problem; also known as instillation of hope.</td>
</tr>
<tr>
<td>Interaction</td>
<td>The free and open exchange of ideas and feelings among group members; effective interaction is emotionally charged.</td>
</tr>
<tr>
<td>Interpretation</td>
<td>The process during which the group leader formulates the meaning or significance of a patient's resistance, defenses, and symbols; the result is that the patient has a cognitive framework within which to understand his or her behavior.</td>
</tr>
<tr>
<td>Learning</td>
<td>Patients acquire knowledge about new areas, such as social skills and sexual behavior; they receive advice, obtain guidance, and attempt to influence and are influenced by other group members.</td>
</tr>
<tr>
<td>Reality testing</td>
<td>Ability of the person to evaluate objectively the world outside the self; includes the capacity to perceive oneself and other group members accurately. See also Consensual validation.</td>
</tr>
<tr>
<td>Transference</td>
<td>Projection of feelings, thoughts, and wishes onto the therapist, who has come to represent an object from the patient's past. Such reactions, while perhaps appropriate for the condition prevailing in the patient's earlier life, are inappropriate and anachronistic when applied to the therapist in the present. Patients in the group may also direct such feelings toward one another, a process called multiple transferences.</td>
</tr>
<tr>
<td>Universalization</td>
<td>The awareness of the patient that he or she is not alone in having problems; others share similar complaints or difficulties in learning; the patient is not unique.</td>
</tr>
<tr>
<td>Ventilation</td>
<td>The expression of suppressed feelings, ideas, or events to other group members; the sharing of personal secrets that ameliorate a sense of sin or guilt (also referred to as self-disclosure).</td>
</tr>
</tbody>
</table>

**ROLE OF THE THERAPIST**

Although opinions differ about how active or passive a group therapist should be, the consensus is that the therapist's role is primarily facilitative. Ideally, the group members themselves are the primary source of cure and change. The climate produced by the therapist's personality is a potent agent of change. The therapist is more than an expert
applying techniques; he or she exerts a personal influence that taps such variables as empathy, warmth, and respect.

INPATIENT GROUP PSYCHOTHERAPY

Group therapy is an important part of hospitalized patients’ therapeutic experiences. Groups can be organized in many ways on a ward. In a community meeting, an entire inpatient unit meets with all the staff members (e.g., psychiatrists, psychologists, and nurses). In team meetings, 15 to 20 patients and staff members meet; a regular or small group comprising eight to ten patients may meet with one or two therapists, as in traditional group therapy. Although the goals of each group vary, they all have common purposes: to increase patients’ awareness of themselves through their interactions with the other group members, who provide feedback about their behavior; to provide patients with improved interpersonal and social skills; to help the members adapt to an inpatient setting; and to improve communication between patients and staff. In addition, one type of group meeting is attended only by inpatient hospital staff and is meant to improve communication among the staff members and to provide mutual support and encouragement in their day-to-day work with patients. Community meetings and team meetings are more helpful for dealing with patient treatment problems than they are for providing insight-oriented therapy, which is the province of the small-group therapy meeting.

Group Composition

Two key factors of inpatient groups common to all short-term therapies are the heterogeneity of the members and the rapid turnover of patients. Outside the hospital, therapists have large caseloads from which to select patients for group therapy. On the ward, therapists have a limited number of patients to choose from and are further restricted to those patients who are both willing to participate and suitable for a small-group experience. In certain settings, group participation may be mandatory (e.g., in substance abuse and alcohol dependence units), but mandatory attendance does not usually apply in a general psychiatry unit. In fact, most group experiences are more productive when the patients themselves choose to enter them.

More sessions are preferable to fewer. During patients’ hospital stays, groups may meet daily to allow interactional continuity and the carryover of themes from one session to the next. A new member of a group can be brought up to date quickly, either by the therapist in an orientation meeting or by one of the members. A newly admitted patient has often learned many details about the small-group program from another patient before actually attending the first session. The less frequently the group sessions are held, the greater the need for a therapist to structure the group and be active in it.

Inpatient versus Outpatient Groups

Although the therapeutic factors that account for change in small inpatient groups are
similar to those in the outpatient settings, there are qualitative differences. For example, the relatively high turnover of patients in inpatient groups complicates the process of cohesion. But the fact that all the group members are together in the hospital aids cohesion, as do the therapists’ efforts to foster the process. Sharing of information, universalization, and catharsis are the main therapeutic factors at work in inpatient groups. Although insight more likely occurs in outpatient groups because of their long-term nature, some patients can obtain a new understanding of their psychological makeup within the confines of a single group session. A unique quality of inpatient groups is the patients’ extragroup contacts, which are extensive because they live together on the same ward. Verbalizing their thoughts and feelings about such contacts in the therapy sessions encourages interpersonal learning. In addition, conflicts between patients or between patients and staff members can be anticipated and resolved.

Twelve former psychiatric inpatients who attended the monthly medication clinic would meet for 1 hour before their individual appointments with the psychiatrist to review their current social situation and medications. All had been treated by the same ward doctor and had known one another while on the inpatient service. The psychiatrist who performed the medication reviews also served as the group leader. Periodically, he was assisted by a staff member who was also familiar with the patients. Coffee was available, and the patients often brought pastries from home. The patients socialized with one another during the hour and frequently exchanged helpful ideas and tips about job opportunities. Those without cars shared rides with other members. The group was open ended and well attended. Most of the patients were single and had a long history of psychotic illness. For most, this meeting was their only opportunity to socialize and be among peers. Frequently, on learning that a member had been rehospitalized, many in the group would visit their colleague on the ward. (Courtesy of Normund Wong, M.D.)

**SELF-HELP GROUPS**

Self-help groups comprise persons who are trying to cope with a specific problem or life crisis and are usually organized with a particular task in mind. Such groups do not attempt to explore individual psychodynamics in great depth or to change personality functioning significantly, but self-help groups have improved the emotional health and well-being of many persons.

A distinguishing characteristic of the self-help groups is their homogeneity. The members have the same disorders and share their experiences—good and bad, successful and unsuccessful—with one another. By so doing, they educate one another, provide mutual support, and alleviate the sense of alienation usually felt by persons drawn to this kind of group.

Self-help groups emphasize cohesion, which is exceptionally strong in these groups. Because the group members have similar problems and symptoms, they develop a strong
emotional bond. Each group may have its unique characteristics, to which the members can attribute magical qualities of healing. Examples of self-help groups are Alcoholics Anonymous (AA), Gamblers Anonymous (GA), and Overeaters Anonymous (OA).

The self-help group movement is presently in ascendancy. These groups meet their members’ needs by providing acceptance, mutual support, and help in overcoming maladaptive patterns of behavior or states of feeling that traditional mental health and medical professionals have not generally dealt with successfully. Self-help groups and therapy groups have begun to converge. Self-help groups have enabled their members to give up patterns of unwanted behavior; therapy groups have helped their members understand why and how they got to be the way they were or are.

COMBINED INDIVIDUAL AND GROUP PSYCHOTHERAPY

In combined individual and group psychotherapy, patients see a therapist individually and also take part in group sessions. The therapist for the group and individual sessions is usually the same person. Groups can vary in size from 3 to 15 members, but the most helpful size is 8 to 10. Patients must attend all group sessions. Attendance at individual sessions is also important, and failure to attend either group or individual sessions should be examined as part of the therapeutic process.

Combined therapy is a particular treatment modality, not a system by which individual therapy is augmented by an occasional group session or a group therapy in which a participant meets alone with a therapist from time to time. Rather, it is an ongoing plan in which meaningful integration of the group experience with the individual sessions yields reciprocal feedback to help form an integrated therapeutic experience. Although the one-to-one doctor–patient relationship makes a deep examination of the transference reaction possible for some patients, it may not provide other patients with the corrective emotional experiences necessary for therapeutic change. The group gives patients a variety of persons with whom they can have transferential reactions. In the microcosm of the group, patients can relive and work through familial and other important influences.

Techniques

Differing techniques based on varying theoretical frameworks have been used in the combined therapy format. Some clinicians increase the frequency of individual sessions to encourage the emergence of the transference neurosis. In the behavioral model, individual sessions are scheduled regularly, but they tend to be less frequent than in other approaches. Whether patients use a couch or a chair during individual sessions depends on a therapist’s orientation. Techniques such as alternate meetings or “after-sessions” without the therapist present may be used. A combined therapy approach called structured interactional group psychotherapy has a different group member as the focus of each weekly group session who is discussed in depth by the other members.
Results
Most workers in the field believe that combined therapy has the advantages of both dyadic and group settings, without sacrificing the qualities of either. Generally, the dropout rate in combined therapy is lower than that in group therapy alone. In many cases, combined therapy appears to bring problems to the surface and to resolve them more quickly than might be possible with either method alone.

PSYCHODRAMA
Psychodrama is a method of group psychotherapy originated by the Viennese-born psychiatrist Jacob Moreno in which personality makeup, interpersonal relationships, conflicts, and emotional problems are explored by means of special dramatic methods. Therapeutic dramatization of emotional problems includes the protagonist or patient, the person who acts out problems with the help of auxiliary egos, persons who enact varying aspects of the patient, and the director, psychodramatist, or therapist, the person who guides those in the drama toward the acquisition of insight.

Roles
Director. The director is the leader or therapist and so must be an active participant. He or she has a catalytic function by encouraging the members of the group to be spontaneous. The director must also be available to meet the group’s needs without superimposing his or her values. Of all the group psychotherapies, psychodrama requires the most participation from the therapist.

Protagonist. The protagonist is the patient in conflict. The patient chooses the situation to portray in the dramatic scene, or the therapist chooses it if the patient so desires.

Auxiliary Ego. An auxiliary ego is another group member who represents something or someone in the protagonist’s experience. The auxiliary egos help account for the great range of therapeutic effects available in psychodrama.

Group. The members of the psychodrama and the audience make up the group. Some are participants, and others are observers, but all benefit from the experience to the extent that they can identify with the ongoing events. The concept of spontaneity in psychodrama refers to the ability of each member of the group, especially the protagonist, to experience the thoughts and feelings of the moment and to communicate emotion as authentically as possible.

Techniques
The psychodrama can focus on any special area of functioning (a dream, a family, or a
community situation), a symbolic role, an unconscious attitude, or an imagined future situation. Such symptoms as delusions and hallucinations can also be acted out in the group. Techniques to advance the therapeutic process and to increase productivity and creativity include the soliloquy (a recital of overt and hidden thoughts and feelings), role reversal (the exchange of the patient’s role for the role of a significant person), the double (an auxiliary ego acting as the patient), the multiple double (several egos acting as the patient did on varying occasions), and the mirror technique (an ego imitating the patient and speaking for him or her). Other techniques include the use of hypnosis and psychoactive drugs to modify the acting behavior in various ways.

ETHICAL AND LEGAL ISSUES

Confidentiality

Except where disclosure is required by law, the group therapist legally and ethically gives information about the group members to others only after obtaining appropriate patient consent. The therapist is obligated to take appropriate steps to be responsible to society, as well as to patients, when patients pose a danger to themselves or to others. The guidelines for ethics of the American Group Psychotherapy Association state that therapists must obtain specific permission to confer with the referring therapist or with the individual therapist when the patient is in conjoint therapy.

Although the group members, as well as the therapist, should protect the identity of the members and maintain confidentiality, the group members are not legally bound to do so. During the preparation of patients for group psychotherapy, therapists should routinely instruct the prospective members to keep all material discussed in the group confidential. Theoretically, in a legal case, one member of a group can be asked to testify against another, but such a situation has not yet occurred.

A therapist must exercise clinical judgment and caution in placing a patient in a group if he or she thinks that the burdens of maintaining secrets will be too great for some potential members or if a prospective group patient harbors a secret of such magnitude or notoriety that membership in a group would not be wise.

Violence and Aggression

Although reports of violence and aggression are rare, the potential exists that a group member may physically attack another patient or a therapist. The attack may occur within the group or outside the group. The likelihood of such an event can be diminished through the careful selection of group members. Patients with a demonstrated history of assaultive behavior and psychotic patients who pose a potential for violence should not be placed in a group. In institutional settings, in which group therapy is commonly practiced, sufficient safeguards must be in place to discourage any physical danger to others—for example, guards or attendants can act as observers.

Sexual Behavior
For therapists, sexual intercourse with a patient or a former patient is unethical; in many states, such behavior is considered a criminal act. The issue is complicated in group psychotherapy, however, because members may engage in sexual activities with one another. The issues of pregnancy, rape, and the transmission of acquired immunodeficiency syndrome (AIDS) by group members are open questions. If a patient is injured as a result of sexual activity by group members, the therapist could be held accountable for not preventing such behavior. The therapist should advise prospective group members that each patient is responsible for reporting any sexual contact between members. The therapist cannot anticipate every group sexual encounter or prevent sexual relationships from developing, but he or she is obligated to provide patients with guidelines of acceptable behavior. The therapist should identify sexual, vulnerable, or exploitive patients in the selection and preparation of patients for the group. Sociopathic patients who sexually exploit others should be informed that such behavior is explicitly not acceptable in the group and that such behavior should be verbalized rather than acted out. The group must be conducted in such a way that the therapist does not encourage or tacitly allow sexual activity. Patients with AIDS are encouraged to reveal that they harbor the virus. To protect members if sexual relationships occur, some therapists do not accept patients with AIDS into a group unless they agree to reveal their condition. In those situations, the therapist discusses the issue of AIDS with the patient and the group into which the patient is to be placed.

28.4 Family Therapy and Couples Therapy

FAMILY THERAPY

The family is the foundation on which most societies are built. The study of families in different cultures has been a subject of fascination and scientific interest from viewpoints as diverse as sociology, group dynamics, anthropology, ethnicity, race, evolutionary biology, and, of course, the mental health field. The confluence of information gleaned from family studies has set the backdrop against which the contemporary practice of family therapy has evolved.

Family therapy can be defined as any psychotherapeutic endeavor that explicitly focuses on altering the interactions between or among family members and seeks to improve the functioning of the family as a unit, or its subsystems, and the functioning of individual members of the family. Both family therapy and couple therapy aim at some change in relational functioning. In most cases, they also aim at some other change, typically in the functioning of specific individuals in the family. Family therapy meant to heal a rift between parents and their adult children is an example of the use of family therapy centered on relationship goals. Family therapy aimed at increasing the family’s coping with schizophrenia and at reducing the family’s expressed emotion is an example of family therapy aimed at individual goals (in this case, the functioning of the person with schizophrenia), as well as family goals. In the early years of family therapy, change in the family system was seen as being sufficient to produce individual change. More recent treatments aimed at change in individuals, as well as in the family system, tend to supplement the interventions that focus on interpersonal relationships with specific strategies that focus on individual behavior.

Indications

The presence of a relational difficulty is a clear indication for family and couple therapy. Couples and family therapies are the only treatments that have been shown to be efficacious for such problems as marital maladjustment, and other methods, such as individual therapy, have been shown to often have deleterious effects in these situations. Couples and family therapy has also been demonstrated to have a clear and important role in the treatment of numerous specific psychiatric disorders, often as a component within a multimethod treatment.

Of course, as with any therapy, the indications for family and couple therapy are broad and vary from case to case. Family therapy is a therapeutic collage of ideas regarding the underpinnings of family and individual stability and change, psychopathology, and problems in living, as well as relational ethics. Family therapy might better be called systemically sensitive therapy and, in this sense, reflects a basic
worldview as much as a clinical treatment methodology. For therapists thus inclined, then, all clinical problems involve salient interactional components; thus, some kind of family (or other functionally significant other’s) involvement in therapy is always called for, even in treatment that emphasizes individual problems.

An impressive array now exists of common clinical disorders and problems, including child, adolescent, and adult disorders, for which research has demonstrated family or couple treatment methods to be effective. In a few instances, couple and family interventions are probably even the treatment of choice, and for several disorders, the research argues for family intervention to be an essential part of treatment.

**Techniques**

**Initial Consultation.** Family therapy is familiar enough to the general public for families with a high level of conflict to request it specifically. When the initial complaint is about an individual family member, however, pretreatment work may be needed. Underlying resistance to a family approach typically includes fears by parents that they will be blamed for their child’s difficulties, that the entire family will be pronounced sick, that a spouse will object, and that open discussion of one child’s misbehavior will have a negative influence on siblings. Refusal by an adolescent or young adult patient to participate in family therapy is frequently a disguised collusion with the fears of one or both parents.

**Interview Technique.** The special quality of a family interview springs from two important facts. A family comes to treatment with its history and dynamics firmly in place. To a family therapist, the established nature of the group, more than the symptoms, constitutes the clinical problem. Family members usually live together and, at some level, depend on one another for their physical and emotional well-being. Whatever transpires in the therapy session is known to all. Central principles of technique also derive from these facts. For example, the therapist must carefully channel the catharsis of anger by one family member toward another. The person who is the object of the anger will react to the attack, and the anger may escalate into violence and fracture relationships, with one or more member withdrawing from therapy. For another example, free association is inappropriate in family therapy because it can encourage one person to dominate a session. Thus, therapists must always control and direct the family interview.

Table 28.4-1 summarizes the principles in which the history of the family is examined in an effort to understand how that history informs the current familial interactions.

<table>

<tr>
<th>Table 28.4-1</th>
<th>Rationale for Family-Life Chronology</th>
</tr>
</thead>
</table>
Frequency and Length of Treatment.  Unless an emergency arises, sessions are usually held no more than once a week. Each session, however, may require as much as 2 hours. Long sessions can include an intermission to give the therapist time to organize the material and plan a response. A flexible schedule is necessary when geography or personal circumstances make it physically difficult for the family to get together. The length of treatment depends both on the nature of the problem and on the therapeutic model. Therapists who use problem-solving models exclusively may accomplish their goals in a few sessions, whereas therapists using growth-oriented models may work with a family for years and may schedule sessions at long intervals. Table 28.4-2 summarizes one model for treatment termination.

Table 28.4-2
Criteria for Treatment Termination
Models of Intervention

Many models of family therapy exist, none of which is superior to the others. The particular model used depends on the training received, the context in which therapy occurs, and the personality of the therapist.

Psychodynamic-Experiential Models. Psychodynamic-experiential models emphasize individual maturation in the context of the family system and are free from unconscious patterns of anxiety and projection rooted in the past. Therapists seek to establish an intimate bond with each family member, and sessions alternate between the therapist’s exchanges with the members and the members’ exchanges with one another. Clarity of communication and honestly admitted feelings are given high priority. Toward this end, family members may be encouraged to change their seats, to touch each other, and to make direct eye contact. Their use of metaphor, body language, and parapraxes helps reveal the unconscious pattern of family relationships. The therapist may also use family sculpting, in which family members physically arrange one another in tableaus depicting their personal view of relationships, past or present. The therapist both interprets the living sculpture and modifies it in a way to suggest new relationships. In addition, the therapist’s subjective responses to the family are given great importance. At appropriate moments, the therapist expresses these responses to the family to form yet another feedback loop of self-observation and change.

Bowen Model. Murray Bowen called his model family systems, but in the family therapy field it rightfully carries the name of its originator. The hallmark of the Bowen model is persons’ differentiation from their family of origin, their ability to be their true selves in the face of familial or other pressures that threaten the loss of love or social position. Problem families are assessed on two levels: the degree of their enmeshment versus the degree of their ability to differentiate and the analysis of emotional triangles in the problem for which they seek help.

An emotional triangle is defined as a three-party system (and many of these can exist...
within a family) arranged so that the closeness of two members expressed as either love or repetitive conflict tends to exclude a third. When the excluded third person attempts to join with one of the other two or when one of the involved parties shifts in the direction of the excluded one, emotional cross-currents are activated. The therapist's role is, first, to stabilize or shift the “hot” triangle—the one producing the presenting symptoms—and, second, to work with the most psychologically available family members, individually if necessary, to achieve sufficient personal differentiation so that the hot triangle does not recur. To preserve his or her neutrality in the family’s triangles, the therapist minimizes emotional contact with family members.

Bowen also originated the genogram, a theoretical tool that is a historical survey of the family, going back several generations.

**Structural Model.** In a structural model, families are viewed as single, interrelated systems assessed in terms of significant alliances and splits among family members, hierarchy of power (parents in charge of children), clarity and firmness of boundaries between the generations, and family tolerance for one another. The structural model uses concurrent individual and family therapy.

**General Systems Model.** Based on general systems theory, a general systems model holds that families are systems and that every action in a family produces a reaction in one or more of its members. Families have external boundaries and internal rules. Every member is presumed to play a role (e.g., spokesperson, persecutor, victim, rescuer, symptom bearer, nurturer), which is relatively stable, but which member fills each role may change. Some families try to scapegoat one member by blaming him or her for the family’s problems (the identified patient). If the identified patient improves, another family member may become the scapegoat. The general systems model overlaps with some of the other models presented, particularly the Bowen and structural models.

**Modifications of Techniques**

**Family Group Therapy.** Family group therapy combines several families into a single group. Families share mutual problems and compare their interactions with those of the other families in the group. Treatment of schizophrenia has been effective in multiple family groups. Parents of disturbed children may also meet together to share their situations.

**Social Network Therapy.** In social network therapy, the social community or network of a disturbed patient meets in group sessions with the patient. The network includes those with whom the patient comes into contact in daily life, not only the immediate family but also relatives, friends, tradespersons, teachers, and coworkers.

**Paradoxical Therapy.** With the paradoxical therapy approach, which evolved from the work of Gregory Bateson, a therapist suggests that the patient intentionally
engage in the unwanted behavior (called the paradoxical injunction) and, for example, avoid a phobic object or perform a compulsive ritual. Although paradoxical therapy and the use of paradoxical injunctions seem to be counterintuitive, the therapy can create new insights for some patients. It is used in individual therapy as well as in family therapy.

**Reframing.** Reframing, also known as *positive connotation*, is a relabeling of all negatively expressed feelings or behavior as positive. When the therapist attempts to get family members to view behavior from a new frame of reference, “This child is impossible” becomes “This child is desperately trying to distract and protect you from what he or she perceives as an unhappy marriage.” Reframing is an important process that allows family members to view themselves in new ways that can produce change.

**Goals**

Family therapy has several goals: to resolve or reduce pathogenic conflict and anxiety within the matrix of interpersonal relationships; to enhance the perception and fulfillment by family members of one another’s emotional needs; to promote appropriate role relationships between the sexes and generations; to strengthen the capacity of individual members and the family as a whole to cope with destructive forces inside and outside the surrounding environment; and to influence family identity and values so that members are oriented toward health and growth. The therapy ultimately aims to integrate families into the large systems of society, extended family, and community groups and social systems, such as schools, medical facilities, and social, recreational, and welfare agencies.

**COUPLES (MARITAL) THERAPY**

Couples or marital therapy is a form of psychotherapy designed to psychologically modify the interaction of two persons who are in conflict with each other over one parameter or a variety of parameters—social, emotional, sexual, or economic. In couples therapy, a trained person establishes a therapeutic contract with a patient-couple and, through definite types of communication, attempts to alleviate the disturbance, to reverse or change maladaptive patterns of behavior, and to encourage personality growth and development.

Marriage counseling may be considered more limited in scope than marriage therapy: Only a particular familial conflict is discussed, and the counseling is primarily task oriented, geared to solving a specific problem, such as child rearing. Marriage therapy, by contrast, emphasizes restructuring a couple’s interaction and sometimes explores the psychodynamics of each partner. Both therapy and counseling stress helping marital partners cope effectively with their problems. Most important is the definition of appropriate and realistic goals, which may involve extensive reconstruction of the union or problem-solving approaches or a combination of both.
Types of Therapies

**Individual Therapy.**  In individual therapy, the partners may consult different therapists, who do not necessarily communicate with each other and indeed may not even know each other. The goal of treatment is to strengthen each partner's adaptive capacities. At times, only one of the partners is in treatment; and, in such cases, it is often helpful for the person who is not in treatment to visit the therapist. The visiting partner may give the therapist data about the patient that may otherwise be overlooked; overt or covert anxiety in the visiting partner as a result of change in the patient can be identified and dealt with; irrational beliefs about treatment events can be corrected; and conscious or unconscious attempts by the partner to sabotage the patient's treatment can be examined.

**Individual Couples Therapy.**  In individual couples therapy, each partner is in therapy, which is either concurrent, with the same therapist, or collaborative, with each partner seeing a different therapist.

**Conjoint Therapy.**  In conjoint therapy, the most common treatment method in couples therapy, either one or two therapists treat the partners in joint sessions. Cotherapy with therapists of both sexes prevents a particular patient from feeling ganged up on when confronted by two members of the opposite sex.

**Four-Way Session.**  In a four-way session, each partner is seen by a different therapist, with regular joint sessions in which all four persons participate. A variation of the four-way session is the roundtable interview, developed by William Masters and Virginia Johnson for the rapid treatment of sexually dysfunctional couples. Two patients and two opposite-sex therapists meet regularly.

**Group Psychotherapy.**  Group therapy for couples allows a variety of group dynamics to affect the participants. Groups usually consist of three to four couples and one or two therapists. The couples identify with one another and recognize that others have similar problems; each gains support and empathy from fellow group members of the same or opposite sex. They explore sexual attitudes and have an opportunity to gain new information from their peer groups, and each receives specific feedback about his or her behavior, either negative or positive, which may have more meaning and be better assimilated coming from a neutral, nonspouse member, for example, than from the spouse or the therapist.

During the middle phase of a couples group comprising four couples, the theme of whether to have children arose. One couple had just come from a visit to the gynecologist, who informed them that they were running out of time because of the wife’s age. The woman in the couple did not want to have children, but her husband
did. His complaint about the marriage was that his wife never was demonstrative in showing her loving feelings for him. He felt her to be detached, distant, and sexually inhibited.

The prevailing sentiment among the other couples who had children was that children only added additional stress to an already stressed relationship. One other couple, however, voiced their different view by describing how their children had enriched their lives.

As the talk about going forward and getting pregnant progressed, the group leader noted the nonverbal communication between the ambivalent couple. Whenever the tone of the group leaned toward having children, the wife would reach out and grasp the hand of her husband in a tender way. This invariably had the effect of stopping him from pursuing the topic for fear of the withdrawal of the affection he hungered for. All this occurred without words. Once identified, this repetitive nonverbal pattern was available for examination in the group, and the supportive elements provided by other members and the leader encouraged a frank, direct, and open conversation between the partners, who eventually chose to go forward and attempt to have a child. (Courtesy of H. I. Spitz, M.D., and S. Spitz, ACSW.)

**Combined Therapy.** Combined therapy refers to all or any of the preceding techniques used concurrently or in combination. Thus, a particular patient-couple may begin treatment with one or both partners in individual psychotherapy, continue in conjoint therapy with the partner, and terminate therapy after a course of treatment in a married couples’ group. The rationale for combined therapy is that no single approach to marital problems has been shown to be superior to another. A familiarity with a variety of approaches thus allows therapists a flexibility that provides maximal benefit for couples in distress.

**Indications**
Whatever the specific therapeutic technique, initiation of couples therapy is indicated when individual therapy has failed to resolve the relationship difficulties, when the onset of distress in one or both partners is clearly a relational problem, and when couples therapy is requested by a couple in conflict. Problems in communication between partners are a prime indication for couples therapy. In such instances, one spouse may be intimidated by the other, may become anxious when attempting to tell the other about thoughts or feelings, or may project unconscious expectations onto the other. The therapy is geared toward enabling each partner to see the other realistically. Conflicts in one or several areas, such as the partners’ sexual life, are also indications for treatment. Similarly, difficulty in establishing satisfactory social, economic, parental, or emotional roles implies that a couple needs help. Clinicians should evaluate all aspects of the marital relationship before attempting to treat only one problem, which could be a symptom of a pervasive marital disorder.
Contraindications

Contraindications for couples therapy include patients with severe forms of psychosis, particularly patients with paranoid elements and those in whom the marriage’s homeostatic mechanism is a protection against psychosis, marriages in which one or both partners really want to divorce, and marriages in which one spouse refuses to participate because of anxiety or fear.

Goals

Nathan Ackerman defined the aims of couples therapy as follows: The goals of therapy for partner relational problems are to alleviate emotional distress and disability and to promote the levels of well-being of both partners together and of each as an individual. Ideally, therapists move toward these goals by strengthening the shared resources for problem solving, by encouraging the substitution of adequate controls and defenses for pathogenic ones, by enhancing both the immunity against the disintegrative effects of emotional upset and the complementarity of the relationship, and by promoting the growth of the relationship and of each partner.

Part of a therapist’s task is to persuade each partner in the relationship to take responsibility in understanding the psychodynamic makeup of personality. Each person’s accountability for the effects of behavior on his or her own life, the life of the partner, and the lives of others in the environment is emphasized, and the result is often a deep understanding of the problems that created the marital discord.

Couples therapy does not ensure the maintenance of any marriage or relationship. Indeed, in certain instances, it may show the partners that they are in a nonviable union that should be dissolved. In these cases, couples may continue to meet with therapists to work through the difficulties of separating and obtaining a divorce, a process that has been called divorce therapy.

28.5 Dialectical Behavior Therapy

Dialectical behavior therapy (DBT) is the psychosocial treatment that has received the most empirical support for patients with borderline personality disorder. Put simply, the overarching goal of DBT is to help create a life worth living for patients who often suffer tremendously from chronic and pervasive problems across many areas of their lives. DBT is a type of psychotherapy that was originally developed for chronically self-injurious patients with borderline personality disorder and parasuicidal behavior. In recent years, its use has extended to other forms of mental illness. The method is eclectic, drawing on concepts derived from supportive, cognitive, and behavioral therapies. Some elements can be traced to Franz Alexander’s view of therapy as a corrective emotional experience and other elements from certain Eastern philosophical schools (e.g., Zen).

Patients are seen weekly, with the goal of improving interpersonal skills and decreasing self-destructive behavior using techniques involving advice, metaphor, storytelling, and confrontation, among others. Patients with borderline personality disorder especially are helped to deal with the ambivalent feelings that are characteristic of the disorder. Marsha Linehan, Ph.D., developed the treatment method, based on her theory that such patients cannot identify emotional experiences and cannot tolerate frustration or rejection. As with other behavioral approaches, DBT assumes all behavior (including thoughts and feelings) is learned and that patients with borderline personality disorder behave in ways that reinforce or even reward their behavior, regardless of how maladaptive it is.

FUNCTIONS OF DBT

As described by its originator, there are five essential “functions” in treatment: (1) to enhance and expand the patient’s repertoire of skillful behavioral patterns; (2) to improve patient motivation to change by reducing reinforcement of maladaptive behavior, including dysfunctional cognition and emotion; (3) to ensure that new behavioral patterns generalize from the therapeutic to the natural environment; (4) to structure the environment so that effective behaviors, rather than dysfunctional behaviors, are reinforced; and (5) to enhance the motivation and capabilities of the therapist so that effective treatment is rendered. Figure 28.5-1 illustrates how DBT breaks the cycle of problem behavior being used to avoid emotional distress.
The four modes of treatment in DBT are as follows: (1) group skills training, (2) individual therapy, (3) phone consultations, and (4) consultation team. These are described below. Other ancillary treatments used are pharmacotherapy and hospitalization, when needed.

**Group Skills Training**
In group format, patients learn specific behavioral, emotional, cognitive, and interpersonal skills. Unlike traditional group therapy, observations about others in the group are discouraged. Rather, a didactic approach, using specific exercises taken from a skills training manual, is used, many of which are geared toward control emotional dysregulation and impulsive behavior.

**Individual Therapy**
Sessions in DBT are held weekly, generally for 50 to 60 minutes, in which skills learned during group training are reviewed and life events from the previous week are examined. Particular attention is paid to episodes of pathological behavioral patterns that could have been corrected if learned skills had been put into effect. Patients are
encouraged to record their thoughts, feelings, and behaviors on diary cards, which are analyzed in the session.

**Telephone Consultation**

Therapists are available for phone consultation 24 hours per day. Patients are encouraged to call when they feel themselves heading toward some crisis that might lead to injurious behavior to themselves or others. Calls are intended to be brief and usually last about 10 minutes.

**Consultation Team**

Therapists meet in weekly meetings to review their work with their patients. By doing so, they provide support for one another and maintain motivation in their work. The meetings enable them to compare techniques used and to validate those that are most effective (Table 28.5-1).

| Table 28.5-1 |
| Consultation Team Agreements in Dialectical Behavior Therapy |

Meet weekly for 1 to 2 hours

Discuss cases according to the treatment hierarchy (i.e., self-injurious/life-threatening behavior, behaviors that interfere with treatment or quality of life).

Accept a dialectical philosophy.

Consult with the patient on how to interact with other therapists, but do not tell other therapists how to interact with the patient.

Consistency of therapists with one another (even across the same patient) is not expected.

All therapists observe their own limits without fear of judgmental reactions from other consultation group members.

Search for nonpejorative empathic interpretation of the patient’s behavior.

All therapists are fallible.

**RESULTS**

Several studies evaluating the effect of DBT for patients with borderline personality disorder found that such therapy was positive. Patients had a low dropout rate from treatment; the incidence of parasuicidal behaviors declined; self-report of angry affect decreased; and social adjustment and work performance improved. The method is now being applied to other disorders, including substance abuse, eating disorders, schizophrenia, and posttraumatic stress disorder.

**REFERENCES**

Biofeedback involves the recording and display of small changes in the physiological levels of the feedback parameter. The display can be visual, such as a big meter or a bar of lights, or auditory. Patients are instructed to change the levels of the parameter, using the feedback from the display as a guide. Biofeedback is based on the idea that the autonomic nervous system can come under voluntary control through operant conditioning. Biofeedback can be used by itself or in combination with relaxation. For example, patients with urinary incontinence use biofeedback alone to regain control over the pelvic musculature. Biofeedback is also used in the rehabilitation of neurological disorders. The benefits of biofeedback may be augmented by the relaxation that patients are trained to facilitate.

THEORY

Neal Miller demonstrated the medical potential of biofeedback by showing that the normally involuntary autonomic nervous system can be operantly conditioned by use of appropriate feedback. By means of instruments, patients acquire information about the status of involuntary biological functions, such as skin temperature and electrical conductivity, muscle tension, blood pressure, heart rate, and brain wave activity. Patients then learn to regulate one or more of these biological states that affect symptoms. For example, a person can learn to raise the temperature of his or her hands to reduce the frequency of migraines, palpitations, or angina pectoris. Presumably, patients lower the sympathetic activation and voluntarily self-regulate arterial smooth muscle vasoconstrictive tendencies.

METHODS

Instrumentation

The feedback instrument used depends on the patient and the specific problem. The most effective instruments are the electromyogram (EMG), which measures the electrical
potentials of muscle fibers; the electroencephalogram (EEG), which measures alpha waves that occur in relaxed states; the galvanic skin response (GSR) gauge, which shows decreased skin conductivity during a relaxed state; and the thermistor, which measures skin temperature (which drops during tension because of peripheral vasoconstriction). Patients are attached to one of the instruments that measures a physiological function and translates the measurement into an audible or visual signal that patients use to gauge their responses. For example, in the treatment of bruxism, an EMG is attached to the masseter muscle. The EMG emits a high tone when the muscle is contracted and a low tone when at rest. Patients can learn to alter the tone to indicate relaxation. Patients receive feedback about the masseter muscle, the tone reinforces the learning, and the condition ameliorates—all of these events interacting synergistically.

Many less-specific clinical applications (e.g., treating insomnia, dysmenorrhea, and speech problems; improving athletic performance; treating volitional disorders; achieving altered states of consciousness; managing stress; and supplementing psychotherapy for treating anxiety associated with somatic symptom and related disorders) use a model in which frontalis muscle EMG biofeedback is combined with thermal biofeedback and verbal instructions in progressive relaxation. Table 28.6-1 outlines some important clinical applications of biofeedback and shows that a wide variety of biofeedback modalities have been used to treat numerous conditions.

| Table 28.6-1 | Biofeedback Applications |
Relaxation Therapy

Muscle relaxation is used as a component of treatment programs (e.g., systematic desensitization) or as treatment in its own right (relaxation therapy). Relaxation is characterized by (1) immobility of the body, (2) control over the focus of attention, (3) low muscle tone, and (4) cultivation of a specific frame of mind, described as contemplative, nonjudgmental, detached, or mindful.

Progressive relaxation was developed by Edmund Jacobson in 1929. Jacobson observed that when an individual lies “relaxed,” in the ordinary sense, the following clinical signs reveal the presence of residual tension: respiration is slightly irregular in time or force; the pulse rate, although often normal, is in some instances moderately increased as compared with later tests; voluntary or local reflex activities are revealed in such slight marks as wrinkling of the forehead, frowning, movements of the eyeballs frequent or rapid winking, restless shifting of the head, a limb, or even a finger; and finally, the mind continues to be active, and once started, worry or oppressive emotion will persist. It is amazing that a faint degree of tension can be responsible for all of this.

Learning relaxation, therefore, involves cultivating a muscle sense. To develop the

<th>Condition</th>
<th>Effects</th>
</tr>
</thead>
<tbody>
<tr>
<td>Asthma</td>
<td>Both frontal electromyogram (EMG) and airway resistance biofeedback have been reported as producing relaxation from the panic associated with asthma, as well as improving air flow rate.</td>
</tr>
<tr>
<td>Cardiac arrhythmias</td>
<td>Specific biofeedback of the electrocardiogram has permitted patients to lower the frequency of premature ventricular contractions.</td>
</tr>
<tr>
<td>Fecal incontinence and enuresis</td>
<td>The timing sequence of internal and external anal sphincters has been measured, using triple lumen rectal catheters providing feedback to incontinent patients to allow them to reestablish normal bowel habits in a relatively small number of biofeedback sessions. An actual precursor of biofeedback dating to 1938 was a buzzer sounding for sleeping enuretic children at the first sign of moisture (the pad and bell).</td>
</tr>
<tr>
<td>Grand mal epilepsy</td>
<td>A number of electroencephalogram (EEG) biofeedback procedures have been used experimentally to suppress seizure activity prophylactically in patients not responsive to anticonvulsant medication. The procedures permit patients to enhance the sensorimotor brain wave rhythm or to normalize brain activity as computed in real-time power spectrum displays.</td>
</tr>
<tr>
<td>Hyperactivity</td>
<td>EEG biofeedback procedures have been used with children with attention-deficit/hyperactivity disorder to train them to reduce their motor restlessness.</td>
</tr>
<tr>
<td>Idiopathic hypertension and orthostatic hypotension</td>
<td>A variety of specific (direct) and nonspecific biofeedback procedures—including blood pressure feedback, galvanic skin response, and foot–hand thermal feedback combined with relaxation procedures—have been used to teach patients to increase or decrease their blood pressure. Some follow-up data indicate that the changes may persist for years and often permit the reduction or elimination of antihypertensive medications.</td>
</tr>
<tr>
<td>Migraine</td>
<td>The most common biofeedback strategy with classic or common vascular headaches has been thermal biofeedback from a digit accompanied by autogenic self-suggestive phrases encouraging hard warming and head cooling. The mechanism is thought to help prevent excessive cerebral artery vasoconstriction, often accompanied by an ischemic prodromal symptom, such as scintillating scotomata, followed by rebound engorgement of arteries and stretching of vessel walls/pain receptors.</td>
</tr>
<tr>
<td>Myofacial and temporomandibular joint (TMJ) pain</td>
<td>High levels of EMG activity over the powerful muscles associated with bilateral TMJs have been decreased, using biofeedback in patients who are jaw clenchers or have bruxism.</td>
</tr>
<tr>
<td>Neuromuscular rehabilitation</td>
<td>Mechanical devices or an EMG measurement of muscle activity displayed to a patient increases the effectiveness of traditional therapies, as documented by relatively long clinical histories in peripheral nerve–muscle damage, spasmolytic torticollis, selected cases of tardive dyskinesia, cerebral palsy, and upper motor neuron hemiplegias.</td>
</tr>
<tr>
<td>Raynaud's syndrome</td>
<td>Cold hands and cold feet are frequent concomitants of anxiety and also occur in Raynaud's syndrome, caused by vasospasm of arterial smooth muscle. A number of studies report that thermal feedback from the hand, an inexpensive and benign procedure compared with surgical sympathectomy, is effective in about 70 percent of cases of Raynaud's syndrome.</td>
</tr>
<tr>
<td>Tension headaches</td>
<td>Muscle contraction headaches are most frequently treated with two large active electrodes spaced on the forehead to provide visual or auditory information about the levels of muscle tension. The forehead electrode placement is sensitive to EMG activity regarding the frontalis and occipital muscles, which the patient learns to relax.</td>
</tr>
</tbody>
</table>
muscle sense further, patients are taught to isolate and contract specific muscles or muscle groups, one at a time. For example, patients flex the forearm while the therapist holds it back to observe tenseness in the biceps muscle. (Jacobson used the word “tenseness” rather than “tension” to emphasize the patient’s role in tensing the muscles.) Once this sensation is reported, Jacobson would say, “This is your doing! What we wish is the reverse of this—simply not doing.” Patients are repeatedly reminded that relaxation involves no effort. In fact “making an effort is being tense and therefore is not to relax.” As the session progresses, patients are instructed to let go further and further, even past the point when the body part seems perfectly relaxed.

Patients would work in this fashion with different muscle groups, often over more than 50 sessions. For example, an entire session might be devoted to relaxing the biceps muscle. Another feature of Jacobson’s method was that instructions were given tersely so they would not interfere with a patient’s focus on muscle sensations; suggestions commonly used today (e.g., “Your arm is becoming limp”) were avoided. Patients were also frequently left alone, while the therapist attended to other patients.

In psychiatry, relaxation therapy is mainly used as a component of multifaceted broad-spectrum programs. Its use in desensitization was mentioned previously. Relaxing breathing exercises are often helpful for patients with panic disorder, especially when considered to be related to hyperventilation. In the treatment of patients with anxiety disorders, relaxation can serve as an occasion-setting stimulus (i.e., as a context of safety in which other specific intervention can be confidently tried).

Later Adaptation of Progressive Muscular Relaxation

Joseph Wolpe chose progressive relaxation as a response incompatible with anxiety when designing his systematic desensitization treatment (discussed below). For this purpose, Jacobson’s original method was too lengthy to be practical. Wolpe abbreviated the program to 20 minutes during the first six sessions (devoting the remainder of these sessions to other things, such as behavioral analysis). In a later modification of progressive relaxation, patients completed work with all the principal muscle groups in one session. The specific muscle groups and instructions for this type of progressive relaxation are listed in Table 28.6-2. Once patients have mastered this procedure (typically after three sessions), these groups are combined into larger groups. Finally, patients practice relaxation by recall (i.e., without tensing the muscles).

| Table 28.6-2 |
| Outline of Initial Progressive Relaxation Session, All Muscle Groups |
Autogenic Training

Autogenic training is a method of self-suggestion that originated in Germany. It involves the patients directing their attention to specific bodily areas and hearing themselves think certain phrases reflecting a relaxed state. In the original German version, patients progressed through six themes over many sessions. The six areas are listed in Table 28.6-3 along with representative autogenic phrases. Autogenic relaxation is an American modification of autogenic training, in which all six areas are covered in one session.

Applied Tension

Applied tension is a technique that is the opposite of relaxation; applied tension can be used to counteract the fainting response. The treatment extends over four sessions. In the first session, patients learn to tense the muscles of the arms, legs, and torso for 10 to 15 seconds (as if they were bodybuilders). The tension is maintained long enough for a sensation of warmth to develop in the face. The patients then release the tension, but do not progress to a state of relaxation. The maneuver is repeated five times at half-minute intervals. This method can be augmented with feedback of the patient’s blood pressure during the muscle contraction; increased blood pressure suggests that appropriate muscle tension was achieved. The patients continue to practice the technique five times.
a day. An adverse effect of treatment that sometimes develops is headache. In this case, the intensity of the muscle contraction and the frequency of treatment are reduced.

Patients with blood and injury phobia show a unique, biphasic response when exposed to a phobic stimulus. The first phase is associated with increased heart rate and blood pressure. In the second phase, however, blood pressure suddenly falls and the patient faints. To treat the problem, patients are shown a series of slides that are provocative (e.g., mutilated bodies). They are coached in identifying early warning signs of fainting, such as queasiness, cold sweats, or dizziness, and in applying the learned muscle tension response quickly, contingent on these warning signs. Patients can also perform applied tension while donating blood or watching a surgical operation. The technique of isometric tension raises blood pressure, which prevents fainting.

**Applied Relaxation**

Applied relaxation involves eliciting a relaxation response in the stressful situation itself. The previous discussion showed that this is not advisable right away because of the possible ironic effects of relaxation. Therefore, patients should first practice relaxation in nonstressful circumstances. The method developed by Lars-Göran Öst and coworkers in Sweden has been proven efficacious for panic disorder and generalized anxiety disorder. Establishing the relaxation response in the patient’s natural environment consists of seven phases of one to two sessions each: progressive relaxation, release-only relaxation, cue-controlled relaxation, differential relaxation, rapid relaxation, application training, and maintenance. Details are provided in Table 28.6-4.

<table>
<thead>
<tr>
<th>Table 28.6-4</th>
<th>Steps in Applied Relaxation</th>
</tr>
</thead>
</table>
Biofeedback, progressive relaxation, and applied tension have been shown to be effective treatment methods for a broad range of disorders. They form one basis of behavioral medicine in which the patient changes (or learns how to change) behavior that contributes to illness. They form a basis on which many complementary and alternative medical procedures are effective (e.g., yoga and Reiki) in which relaxation is an important component. Relaxation also informs more mainstream treatments, such as hypnosis.

<table>
<thead>
<tr>
<th>Technique</th>
<th>Instructions</th>
</tr>
</thead>
</table>
| Progressive relaxation  | Session 1: hands, arms, face, neck, and shoulders  
 Session 2: back, chest, stomach, breathing, hips, legs, and feet |
| Release-only relaxation | As with progressive relaxation, except that the tension phase is omitted; when release-only relaxation is mastered, the patient can relax within 5 to 7 minutes |
| Cue-controlled relaxation | A stimulus—the word relax—is presented just before exhalation; patients focus on their breathing while already in a relaxed state; the therapist says the word inhale just before each inhalation and the word relax just before each exhalation; after approximately five cycles, the patient mentally says these words (optionally dropping the inhale) |
| Differential relaxation | Patients can remain relaxed and move at the same time by differentially keeping muscles unrelated to the movement in a relaxed state; after achieving a relaxed state, patients lift an arm or a leg or look around in the room, while keeping movements and tension in other body parts at a minimum; patients also perform differential relaxation in other settings, including sitting in different chairs, sitting at a desk while writing, talking on the phone, and walking. |
| Rapid relaxation | Patients relax by taking one to three breaths with slow exhalations, thinking the word relax before each exhalation and scanning their bodies for areas of tension; with this practice, relaxation is shortened to 20 to 30 seconds; patients are instructed to relax in this manner 15 to 20 times per day at certain predetermined events in their natural environment (e.g., when they look at a watch or make a telephone call. As a reminder, colored dots might be taped on the watch or phone. After some time, the dots are changed to a different color to keep their reminding power fresh). |
| Application training | Patients relax just before entering the target situation; they stay in the situation for 10 to 15 minutes, using their relaxation skills as a coping technique; patients may initially be accompanied by the therapist; alternatively, if the patient's problem is panic attacks or generalized anxiety, imagery or physical exercise is used to induce fearful sensations, which then are used for application training. |
28.7 Cognitive Therapy

A central feature of the cognitive theory of emotional disorders is its emphasis on the psychological significance of people’s beliefs about themselves, their personal world (including the people in their lives), and their future—the “cognitive triad.” When people experience excessive, maladaptive emotional distress, it is linked to their problematic, stereotypic, biased interpretations pertinent to this cognitive triad of self, world, and future. For example, clinically depressed patients may be prone to believe that they are incapable and helpless and to view others as being judgmental and critical and the future as being bleak and unrewarding. Similarly, patients with anxiety disorders may be apt to see themselves as highly vulnerable, others as more capable, and the future as likely to be characterized by personal disasters.
Although the patient’s viewpoints are flawed and dysfunctional, they nonetheless tend to be perpetuated by cognitive processes that maintain them. Cognitive therapy is a short-term, structured therapy that uses active collaboration between patient and therapist to achieve its therapeutic goals, which are oriented toward current problems and their resolution. Cognitive therapy is used with depression, panic disorder, obsessive-compulsive disorder, personality disorders, and somatoform disorders. Therapy is usually conducted on an individual basis, although group methods are sometimes helpful. A therapist may also prescribe drugs in conjunction with therapy.

The treatment of depression can serve as a paradigm of the cognitive approach. Cognitive therapy assumes that perception and experiencing, in general, are active processes that involve both inspective and introspective data. The patient’s cognitions represent a synthesis of internal and external stimuli. The way persons appraise a situation is generally evident in their cognitions (thoughts and visual images). Those cognitions constitute their stream of consciousness or phenomenal field, which reflects their configuration of themselves, their world, their past, and their future.

Alterations in the content of their underlying cognitive structures affect their affective state and behavioral pattern. Through psychological therapy, patients can become aware of their cognitive distortions. Correction of faulty dysfunctional constructs can lead to clinical improvement.

COGNITIVE THEORY OF DEPRESSION

According to the cognitive theory of depression, cognitive dysfunctions are the core of depression, and affective and physical changes and other associated features of depression are consequences of cognitive dysfunctions. For example, apathy and low energy result from a person’s expectation of failure in all areas. Similarly, paralysis of will stems from a person’s pessimism and feelings of hopelessness. From a cognitive perspective, depression can be explained by the cognitive triad, which explains that negative thoughts are about the self, the world, and the future.

The goal of therapy is to alleviate depression and to prevent its recurrence by helping patients to identify and test negative cognitions, to develop alternative and more flexible schemas, and to rehearse both new cognitive and behavioral responses. Changing the way a person thinks can alleviate the psychiatric disorder.

STRATEGIES AND TECHNIQUES

Therapy is relatively short and lasts about 25 weeks. If a patient does not improve in this time, the diagnosis should be reevaluated. Maintenance therapy can be carried out over years. As with other psychotherapies, therapists’ attributes are important to successful therapy. Therapists must exude warmth, understand the life experience of each patient, and be genuine and honest with themselves and with their patients. They must be able to relate skillfully and interactively with their patients. Cognitive therapists set the agenda at the beginning of each session, assign homework to be performed between sessions, and teach new skills. Therapist and patient collaborate
actively (Table 28.7-1). The three components of cognitive therapy are didactic aspects, cognitive techniques, and behavioral techniques.

</tbody>
</table>

**Didactic Aspects**

The therapy’s didactic aspects include explaining to patients the cognitive triad, schemas, and faulty logic. Therapists must tell patients that they will formulate hypotheses together and test them over the course of the treatment. Cognitive therapy requires a full explanation of the relation between depression and thinking, affect, and behavior, as well as the rationale for all aspects of treatment. This explanation contrasts with psychoanalytically oriented therapies, which require little explanation.

**Cognitive Techniques**

The therapy’s cognitive approach includes four processes: eliciting automatic thoughts, testing automatic thoughts, identifying maladaptive underlying assumptions, and testing the validity of maladaptive assumptions.

**Eliciting Automatic Thoughts.** Automatic thoughts, also called *cognitive distortions*, are cognitions that intervene between external events and a person’s emotional reaction to the event. For example, the belief that “people will laugh at me when they see how badly I bowl” is an automatic thought that occurs to someone who has been asked to go bowling and responds negatively. Another example is the thought “She doesn’t like me” when someone passes in the hall without saying “Hello.” Every psychopathological disorder has its own specific cognitive profile of distorted thought, which, if known, provides a framework for specific cognitive interventions (Table 28.7-2).

**Testing Automatic Thoughts.** Acting as a teacher, a therapist helps a patient test the validity of automatic thoughts. The goal is to encourage the patient to reject inaccurate or exaggerated automatic thoughts after careful examination. Patients often blame themselves when things that are outside their control go awry. The therapist reviews the entire situation with the patient and helps reassign the blame or cause of the unpleasant events. Generating alternative explanations for events is another way of undermining inaccurate and distorted automatic thoughts.

**Identifying Maladaptive Assumptions.** As the patient and therapist continue to identify automatic thoughts, patterns usually become apparent. The patterns represent rules or maladaptive general assumptions that guide a patient’s life. Samples of such rules are “In order to be happy, I must be perfect” and “If anyone doesn’t like me, I’m not lovable.” Such rules inevitably lead to disappointments and failure and, ultimately, to depression (Fig. 28.7-1).

**Testing the Validity of Maladaptive Assumptions.** Testing the accuracy of maladaptive assumptions is similar to testing the validity of automatic thoughts. In a particularly effective test, therapists ask patients to defend the validity of their assumptions. For example, patients may state that they should always work up to their potential, and a therapist may ask “Why is that so important to you?” Table 28.7-3 gives examples of some interventions designed to elicit, identify, test, and correct the cognitive distortions that lead to depressive and other painful affects.

Table 28.7-3
Cognitive Errors Derived from Assumptions
A woman presented for therapy with anger control problems. She had sent a slew of hostile voicemail and e-mail messages to a colleague, had alienated her neighbors with her complaints about noise, and had been asked to leave her bowling league after two physical altercations with members of other teams. A careful review of the patient’s thoughts and beliefs surrounding these situations revealed a common denominator of a sense of mistrust and entitlement. In each situation, she believed that the persons who were the objects of her anger had gone out of their way to mistreat her. Furthermore, she had an exaggerated sense of self-importance represented by beliefs such as, “Nobody has the right to treat me that way,” “I shouldn’t have to deal with these people and their stupidity,” and “I have to show them they can’t ever push me around.” To this patient, her anger was justified, as she was trying to defend herself from the misbehavior of others. However, to the outside observer, the patient was a “loose cannon” who took offense at the drop of a hat and whose behavior was outrageous and indefensible. In therapy, the patient at first was not open to viewing her anger problem in the manner just described. However, as she learned to recognize the activation of her schemas of mistrust and entitlement, she became more willing to consider ways in which she could modify her viewpoints and behaviors. This positive change was facilitated by the therapist’s empathic responses to the patient’s more credible stories of mistreatment she had received from her family, whose abusive behavior gave her the message that she should never trust anyone and that she should never put up with being mistreated again. (Courtesy of C. F. Newman, Ph.D., and A. T. Beck, M.D.)
Behavioral Techniques

Behavioral and cognitive techniques go hand in hand; behavioral techniques test and change maladaptive and inaccurate cognitions. The overall purposes of such techniques are to help patients understand the inaccuracy of their cognitive assumptions and learn new strategies and ways of dealing with issues.

Among the behavioral techniques in cognitive therapy are scheduling activities, mastery and pleasure, graded task assignments, cognitive rehearsal, self-reliance training, role playing, and diversion techniques. One of the first things done in therapy is to schedule activities on an hourly basis. Patients keep records of the activities and review them with the therapist. In addition to scheduling activities, patients are asked to rate the amount of mastery and pleasure their activities bring them. Patients are often surprised to learn that they have much more mastery of activities and enjoy them more than they had thought.

To simplify the situation and allow miniaccomplishments, therapists often break tasks into subtasks, as in graded task assignments, to show patients that they can succeed. In cognitive rehearsal, patients imagine and rehearse the various steps in meeting and mastering a challenge.

Patients (especially inpatients) are encouraged to become self-reliant by doing such
simple things as making their own beds, doing their own shopping, and preparing their own meals. This process is called self-reliance training. Role playing is a particularly powerful and useful technique to elicit automatic thoughts and to learn new behaviors. Diversion techniques are useful in helping patients get through difficult times and include physical activity, social contact, work, play, and visual imagery.

Imagery or thought stoppage can treat impulsive or obsessive behavior. For instance, patients imagine a stop sign with a police officer nearby or another image that evokes inhibition at the same time that they recognize an impulse or obsession that is alien to the ego. Similarly, obesity can be treated by having patients visualize themselves as thin, athletic, trim, and well muscled, and then training them to evoke this image whenever they have an urge to eat. Hypnosis or autogenic training can enhance such imagery. In a technique called guided imagery, therapists encourage patients to have fantasies that can be interpreted as wish fulfillments or attempts to master disturbing affects or impulses.
Cognitive therapy can be used alone in the treatment of mild to moderate depressive disorders or in conjunction with antidepressant medication for major depressive disorder. Studies have clearly shown that cognitive therapy is effective and in some cases is superior or equal to medication alone. It is one of the most useful psychotherapeutic interventions currently available for depressive disorders, and it shows promise in the treatment of other disorders.

Cognitive therapy has also been studied as a way of increasing compliance with lithium (Eskalith) prescription by patients with bipolar I disorder and as an adjunct in treating withdrawal from heroin. Table 28.7-4 outlines Beck’s criteria for determining when cognitive therapy is indicated.

Table 28.7-4
Indications for Cognitive Therapy
Criteria that justify the administration of cognitive therapy alone:
- Failure to respond to adequate trials of two antidepressants
- Partial response to adequate dosages of antidepressants
- Failure to respond or only a partial response to other psychotherapies
- Diagnosis of dysthymic disorder
- Variable mood reactive to emotional events
- Variable mood that correlates with negative cognitions
- Mild somatiform disorders (sleep, appetite, weight, libido)
- Adequate reality testing (i.e., no hallucinations or delusions), span of concentration, and memory function
- Inability to tolerate medication effects or evidence that excessive risk is associated with pharmacotherapy

Features that suggest cognitive therapy alone is not indicated:
- Evidence of coexisting schizophrenia, dementia, substance-related disorders, mental retardation
- Patient has medical illness or is taking medication that is likely to cause depression
- Obvious memory impairment or poor reality testing (hallucinations, delusions)
- History of manic episode (bipolar I disorder)
- History of family member who responded to antidepressant
- History of family member with bipolar I disorder
- Absence of precipitating or exacerbating environmental stresses
- Little evidence of cognitive distortions
- Presence of severe somatiform disorders (e.g., pain disorder)

Indications for combined therapies (medication plus cognitive therapy):
- Partial or no response to trial of cognitive therapy alone
- Partial but incomplete response to adequate pharmacotherapy alone
- Poor compliance with medication regimen
- Historical evidence of chronic maladaptive functioning with depressive syndrome on intermittent basis
- Presence of severe somatiform disorders and marked cognitive distortions (e.g., hopelessness)
- Impaired memory and concentration and marked psychomotor difficulty
- Major depressive disorder with suicidal danger
- History of first-degree relative who responded to antidepressants
- History of manic episode in relative or patient

(Adapted from Beck AT, Rush AJ, Shaw BF, Emery G. Cognitive Therapy of Depression. New York: Guilford; 1979;42.)

REFERENCES

The term behavior in behavior therapy refers to a person’s observable actions and responses. Behavior therapy involves changing the behavior of patients to reduce dysfunction and to improve quality of life. Behavior therapy includes a methodology, referred to as behavior analysis, for the strategic selection of behaviors to change, and a technology to bring about behavior change, such as modifying antecedents or consequences or giving instructions. Behavior therapy has not only influenced mental health care, but, under the rubric of behavioral medicine, it has also made inroads into other medical specialties.

Behavior therapy represents clinical applications of the principles developed in learning theory. Behavioral psychology, or behaviorism, arose in the early 20th century in reaction to the method of introspection that dominated psychology at the time. John B. Watson, the father of behaviorism, had initially studied animal psychology. This background made it a small conceptual leap to argue that psychology should concern itself only with publicly observable phenomena (i.e., overt behavior). According to behavioristic thinking, because mental content is not publicly observable, it cannot be subjected to rigorous scientific inquiry. Consequently, behaviorists developed a focus on overt behaviors and their environmental influences.

Today, different behavioral schools continue to share a focus on verifiable behavior. Behavioral views differ from cognitive views in holding that physical, rather than mental, events control behavior. According to behaviorism, mental phenomena or speculations about them are of little or no scientific interest.

HISTORY

As early as the 1920s, scattered reports about the application of learning principles to the treatment of behavioral disorders began to appear, but they had little effect on the mainstream of psychiatry and clinical psychology. Not until the 1960s did behavior therapy emerge as a systematic and comprehensive approach to psychiatric (behavioral) disorders; at that time, it arose independently on three continents. Joseph Wolpe and his colleagues in Johannesburg, South Africa, used Pavlovian techniques to produce and
eliminate experimental neuroses in cats. From this research, Wolpe developed systematic desensitization, the prototype of many current behavioral procedures for the treatment of maladaptive anxiety produced by identifiable stimuli in the environment. At about the same time, a group at the Institute of Psychiatry of the University of London, particularly Hans Jurgen Eysenck and M. B. Shapiro, stressed the importance of an empirical, experimental approach to understanding and treating individual patients, using controlled, single-case experimental paradigms and modern learning theory. The third origin of behavior therapy was work inspired by the research of Harvard psychologist B. F. Skinner. Skinner's students began to apply his operant-conditioning technology, developed in animal-conditioning laboratories, to human beings in clinical settings.

SYSTEMATIC DESENSITIZATION
Developed by Wolpe, systematic desensitization is based on the behavioral principle of counterconditioning, whereby a person overcomes maladaptive anxiety elicited by a situation or an object by approaching the feared situation gradually, in a psychophysiological state that inhibits anxiety. In systematic desensitization, patients attain a state of complete relaxation and are then exposed to the stimulus that elicits the anxiety response. The negative reaction of anxiety is inhibited by the relaxed state, a process called reciprocal inhibition. Rather than using actual situations or objects that elicit fear, patients and therapists prepare a graded list or hierarchy of anxiety-provoking scenes associated with a patient’s fears. The learned relaxation state and the anxiety-provoking scenes are systematically paired in treatment. Thus, systematic desensitization consists of three steps: relaxation training, hierarchy construction, and desensitization of the stimulus.

Relaxation Training
Relaxation produces physiological effects opposite to those of anxiety: slow heart rate, increased peripheral blood flow, and neuromuscular stability. A variety of relaxation methods have been developed. Some, such as yoga and Zen, have been known for centuries. Most methods use so-called progressive relaxation, developed by the psychiatrist Edmund Jacobson. Patients relax major muscle groups in a fixed order, beginning with the small muscle groups of the feet and working cephalad or vice versa. Some clinicians use hypnosis to facilitate relaxation or use tape-recorded exercise to allow patients to practice relaxation on their own. Mental imagery is a relaxation method in which patients are instructed to imagine themselves in a place associated with pleasant, relaxed memories. Such images allow patients to enter a relaxed state or experience (as Herbert Benson termed it) the relaxation response.

The physiological changes that take place during relaxation are the opposite of those induced by the adrenergic stress responses that are part of many emotions. Muscle tension, respiration rate, heart rate, blood pressure, and skin conductance decrease. Finger temperature and blood flow to the finger usually increase. Relaxation increases
respiratory heart rate variability, an index of parasympathetic tone.

Hierarchy Construction

When constructing a hierarchy, clinicians determine all the conditions that elicit anxiety, and then patients create a hierarchy list of 10 to 12 scenes in order of increasing anxiety. For example, an acrophobic hierarchy may begin with a patient’s imagining standing near a window on the second floor and end with being on the roof of a 20-story building, leaning on a guard rail and looking straight down. Table 28.8-1 provides an example of a hierarchy construction for fear of water and heights.

### Table 28.8-1
Hierarchy Construction (Least Anxious to Most Anxious): Fear of Water and Heights

1. Taking a bath at home.
2. Taking a shower at home.
3. Going into the shallow end of the swimming pool.
4. Starting to swim at the shallow end of the swimming pool, breaststroke only.
5. Swimming at the shallow end, doing the crawl.
6. Jumping into the swimming pool at the shallow end.
7. Jumping into the pool and then doing the crawl.
8. Swimming at the shallow end, first breaststroke, then the crawl.
9. Pushing away from the bars and causing a splash.
10. Swimming in the middle of the pool at a depth of 5 feet 3 inches.
11. Swimming at the shallow end and then at the deep end (10 feet 3 inches).
12. Going into the deep end of the swimming pool.
13. Watching people jump from the diving boards.
14. Standing on a step at the deep end of the pool and making a little jump into the water.
15. Backstroke at the shallow end of the pool.
17. Belly-flop dive at the deep end of the pool.
18. Racing dive at the shallow end of the pool.
19. Racing dive at the deep end of the pool.
20. Swimming three times across the deep end of the pool without stopping:
   a. breaststroke
   b. crawl
   c. backstroke
21. Jumping into the pool at a depth of:
   a. 5 feet 3 inches
   b. 6 feet
   c. 7 feet
22. Several jumps at 6 feet and 7 feet, alternating them, and then remaining at the 7-foot depth.
23. Going onto the first diving board and jumping into the water.
24. Jumping off the first diving board, then diving from the first board.
25. Diving off the first board.
26. Jumping from the first diving board, jumping from the second diving board, then diving from the first diving board.
27. Jumping off the first, second, and third diving boards, then diving from the first diving board.
28. Jumping off the first, second, and third diving boards, then diving from the first and then the second diving board.
29. Jumping off the fourth diving board, then diving off the second diving board.
30. Jumping off the fifth diving board, then diving off the third diving board.
31. Jumping off the fifth diving board, then diving off the fourth diving board.
32. Jumping off the top board, then diving off the fourth diving board.
33. Jumping off the top board, then diving off the fifth diving board.
34. Diving off the top diving board.
35. Random stimuli.
36. Looking around before jumping off the third diving board.
37. Looking around before jumping off the fourth diving board.
38. Looking around before jumping off the fifth diving board.
39. Diving from the fifth diving board and looking around before diving.
40. Diving from the top board and looking around before diving.

**Desensitization of the Stimulus**

In the final step, called *desensitization*, patients proceed systematically through the list from the least to the most anxiety-provoking scene while in a deeply relaxed state. The rate at which patients progress through the list is determined by their responses to the
stimuli. When patients can vividly imagine the most anxiety-provoking scene of the hierarchy with equanimity, they experience little anxiety in the corresponding real-life situation.

**Adjunctive Use of Drugs.** Clinicians have used various drugs to hasten relaxation, but drugs should be used cautiously and only by clinicians trained and experienced in potential adverse effects. Either the ultrarapidly acting barbiturate sodium methohexital (Brevital) or diazepam (Valium) is given intravenously in subanesthetic doses. If the procedural details are followed carefully, almost all patients find the procedure pleasant, with few unpleasant side effects. The advantages of pharmacological desensitization are that preliminary training in relaxation can be shortened, almost all patients can relax adequately, and the treatment itself seems to proceed more rapidly than without the drugs.

**Indications.** Systematic desensitization works best in cases of a clearly identifiable anxiety-provoking stimulus. Phobias, obsessions, compulsions, and certain sexual disorders have been treated successfully with this technique.

**THERAPEUTIC-GRADED EXPOSURE**

Therapeutic-graded exposure is similar to systematic desensitization, except that relaxation training is not involved and treatment is usually carried out in a real-life context. This means that the individual must be brought in contact with (i.e., be exposed to) the warning stimulus to learn firsthand that no dangerous consequences will ensue. Exposure is graded according to a hierarchy. Patients afraid of cats, for example, might progress from looking at a picture of a cat to holding one.

**FLOODING**

Flooding (sometimes called implosion) is similar to graded exposure in that it involves exposing the patient to the feared object in vivo; however, there is no hierarchy. Flooding is based on the premise that escaping from an anxiety-provoking experience reinforces the anxiety through conditioning. Thus, clinicians can extinguish the anxiety and prevent the conditioned avoidance behavior by not allowing patients to escape the situation. Clinicians encourage patients to confront feared situations directly, without a gradual buildup, as in systematic desensitization or graded exposure. No relaxation exercises are used, as in systematic desensitization. Patients experience fear, which gradually subsides after a time. The success of the procedure depends on having patients remain in the fear-generating situation until they are calm and feel a sense of mastery. Prematurely withdrawing from the situation or prematurely terminating the fantasized scene is equivalent to an escape, which then reinforces both the conditioned anxiety and the avoidance behavior and produces the opposite of the desired effect. In a variant, called *imaginal flooding*, the feared object or situation is confronted only in the imagination, not in real life. Many patients refuse flooding because of the psychological
discomfort involved. It is also contraindicated when intense anxiety would be hazardous to a patient (e.g., those with heart disease or fragile psychological adaptation). The technique works best with specific phobias. An example of in vivo flooding is presented in the case study.

The patient was a 33-year-old woman with social fears of eating in public. In particular, she was afraid of being observed by others when chewing and swallowing, particularly at dinner parties. A contrived situation was arranged in which the patient came to the session with a prepared meal and drink. She entered a conference room in which five persons in professional attire were already seated along a table. The patient was instructed to eat her meal in front of these individuals. Between bites, she was instructed to look at them often, and they had been instructed to avoid staring contests. She was not to distract herself from her anxiety symptoms. She was to eat her meal slowly, paying attention to the behavior of the observers and to her anxiety symptoms (e.g., dry mouth or difficulty swallowing). No conversation between the patient and observers was permitted. The observers would look at her and observe her chewing and swallowing behaviors, at times writing comments in a notebook. Occasionally, observers would communicate by whispering to each other, exchanging written notes, or giving knowing glances and smiles.

The only other communication occurred between the patient and therapist, and this was limited to the patient providing her subjective units of distress rating. The session lasted 90 minutes. Note: this situation may seem quite traumatizing. Because the exposure session is long and continues until ratings decline, the patient becomes desensitized. (Courtesy of Rolf G. Jacob, M.D., and William H. Pelham, M.D.)

PARTICIPANT MODELING

In participant modeling, patients learn a new behavior by imitation, primarily by observation, without having to perform the behavior until they feel ready. Just as irrational fears can be acquired by learning, they can be unlearned by observing a fearless model confront the feared object. The technique has been useful with phobic children who are placed with other children of their own age and sex who approach the feared object or situation. With adults, a therapist may describe the feared activity in a calm manner that a patient can identify. Or, the therapist may act out the process of mastering the feared activity with a patient. Sometimes a hierarchy of activities is established, with the least anxiety-provoking activity being dealt with first. The participant-modeling technique has been used successfully with agoraphobia by having a therapist accompany a patient into the feared situation. In a variant of the procedure, called behavior rehearsal, real-life problems are acted out under a therapist’s observation or direction.
The following is a self-report by a patient with a contamination phobia, who is afraid to touch objects for fear of being infected or contaminated. She describes her reactions.

[The therapist] started touching everything very slowly. I was told to follow behind and touch everything she touched. It was like we were spreading the contamination. She touched doorknobs, light switches, walls, pictures, and woodwork. She opened drawers in each bedroom and touched the contents. She opened closets and touched clothes hanging on the rods. She touched the towels and sheets in the linen closet. She went through the children’s rooms, touching dolls, stuffed animals, models, Star Wars figures, Transformers, and books.

[The therapist] kept talking to me quietly and calmly all the time we went along. I had been anxious when we started, but as we continued, my anxiety level decreased. At one point, when I had begun to think the worst was over, she pointed to the attic door and said we were going inside. I said, “No, that’s where the mice were.” She told me I didn’t want to have a place in my home that was off limits. I agreed but became very anxious. It was very hard for me to go inside. I began touching the boxes too, but I was very upset. Then, she put her hands down on the floor and wanted me to do the same. I said, “I can’t. I just can’t.” [The therapist] said, “Yes you can.”

[The therapist] spent several hours with me that day. Before she left, she made a list of things for me to do by myself. Twice a day I was to go through the house touching everything the way she had done with me. I was to invite a friend of mine who had a pet to come and visit and also friends of my children who had pets. (Courtesy of Rolf G. Jacobs, M.D., and William H. Pelham, M.D.)

EXPOSURE TO STIMULI PRESENTED IN VIRTUAL REALITY

Advances in computer technology have made it possible to present environmental cues in virtual reality for exposure treatment. Beneficial effects have been reported with virtual reality exposure of patients with height phobia, fear of flying, spider phobia, and claustrophobia. Much experimental work is being done in the field. One model uses an avatar of the patient walking through a crowded supermarket filled with other avatars (including one of the therapists) as a way of conquering agoraphobia.

ASSERTIVENESS TRAINING

Assertiveness is defined as assertive behavior that enables a person to act in his or her own best interest, to stand up for herself or himself without undue anxiety, to express honest feelings comfortably, and to exercise personal rights without denying the rights of others.

Two types of situations frequently call for assertive behaviors: (1) setting limits on pushy friends or relatives and (2) commercial situations, such as countering a sales pitch or being persistent when returning defective merchandise. Early assertiveness training
programs tended to define specific behaviors as assertive or nonassertive. For example, individuals were encouraged to assert themselves if somebody got in front of them in a supermarket checkout line. Increasing attention is now given to context, that is, what would be assertive behavior in this situation depends on circumstances.

**SOCIAL SKILLS TRAINING**

The negative symptoms in patients with schizophrenia constitute behavioral deficits that go beyond difficulties with assertiveness. These patients have inadequate expressive behaviors and inappropriate stimulus control of their social behaviors (i.e., they do not pick up social cues). Similarly, patients with depression often experience a lack of social reinforcement because of a lack of social skills, and social skills training has been found to be efficacious for depression. Patients with social phobia similarly often have not acquired adolescents’ social skills. In fact, their social defensive behaviors (e.g., avoiding eye contact, making brief statements, and minimizing self-disclosure) increase the probability of the rejection that they fear.

Social skills training programs for patients with schizophrenia cover skills in the following areas: conversation, conflict management, assertiveness, community living, friendship and dating, work and vocation, and medication management. Each of these skills has several components. For example, assertiveness skills include making requests, refusing requests, making complaints, responding to complaints, expressing unpleasant feelings, asking for information, making apologies, expressing fear, and refusing alcohol and street drugs. Each component involves specific steps. For example, conflict management includes skills in negotiating, compromising, tactful disagreeing, responding to untrue accusations, and leaving overly stressful situations. A situation in which conflict management skills might be used is when the patient and a friend decide to go to a movie and their choice of movie differs.

Negotiating and compromising, for example, involves the following steps:

1. Explain one’s viewpoint briefly.
2. Listen to the other person’s viewpoint.
3. Repeat the other person’s viewpoint.
4. Suggest a compromise.

At his initial appointment, Phillip described very serious symptoms of obsessive-compulsive disorder (OCD). He was 23 years old and living at home because he was no longer able to work or go to school. His days were consumed with behaviors related to checking, repeating, and hoarding. Phillip was unable to throw away anything—he saved junk mail, used tissues and napkins, old papers and magazines, and any kind of receipt for fear that he might lose something important. Phillip spent many hours checking his trash, his car, and his home to be sure that he had not thrown away anything important. He also checked everything he wrote (e.g., checks,
school exams and papers, letters and e-mails) to be sure that he had not made a mistake, and he read and reread books, magazines, and articles to be sure he understood the written material adequately. Phillip worried constantly that he had done something wrong and would disappoint his parents. He was also depressed because he was unable to function well in life, and he had tremendous social anxiety that had plagued him for many years, making it difficult to make and keep friends.

By the end of Phillip’s second session, his therapist was beginning to get a good idea of the general nature and severity of his symptoms and some of the maintaining factors. However, to plan the treatment in more detail and to get a better idea of how the symptoms occurred during his daily life, she asked Phillip to keep daily records over the next week using a form that she had prepared for him. The form had a place for recording the amount of time he spent doing rituals each morning, afternoon, and evening, as well as another place to record more details about at least one episode of rituals each day (e.g., what was happening before, during, and after the rituals; see Table 28.8-2).

(Compiled by M. A. Stanley, Ph.D., and D. C. Beidel, Ph.D.)

Phillip’s therapist determined that his difficulties with obsessions, rituals, depression, and social fears reflected a core fear of negative evaluation. Phillip was overly concerned with making mistakes, being imperfect, and disappointing others. Even as a child, Phillip was concerned about not doing well enough, and he had difficulty making friends for fear that others would not like him. His parents, who were highly anxious, provided much adulation when Phillip did things well (e.g., learned to ride a bike, got good grades in school), and they spent much time instructing him about how to improve his performance when an activity or grade was not perfect. As Phillip took on more responsibility at school and with part-time work, he became more concerned about doing things right. He learned that going back and
checking his work relieved his anxiety. He also learned that saving his papers for future checking reassured him that he would be able to fix any unrecognized mistakes at a later time. His parents helped him to reduce his anxiety by reassuring him that he was doing okay. As Phillip progressed from elementary school to junior high school to high school, his workload and anxiety gradually increased, but he was able to manage things with some moderate checking and saving. When he began attending college, however, the workload increased extensively, and he found himself doing even more checking and hoarding to reduce his fears about making mistakes. Phillip began to feel that these behaviors were getting out of control, but he could not stop them. He had to check and recheck to be sure that he was not making mistakes. The cycle of anxiety and ritual reduced anxiety was so powerfully reinforcing that he could not stop. He needed help to break this cycle and to address his persistent fear of negative evaluation.

Phillip’s therapist decided to begin treatment with a course of exposure and response prevention (ERP) to get his obsessions and rituals under control and begin to address his core fear of making mistakes and being evaluated negatively. Given that Phillip’s depression had grown from the disability associated with his OCD, the therapist expected that a successful course of ERP might also help to reduce his depressive symptoms. ERP for Phillip began with a home visit, where the therapist helped him to complete common daily activities with adherence to his RP plan, which included the following:

- **No more checking:** After eating, leave the table immediately without inspecting your plate and the surrounding areas (including under the table and chair) for lost items. Leave the restroom immediately after using it, without checking the toilet, trash, and sink for lost items. When leaving the car, no more checking of seats, floors, and windows. Write everything (papers, checks, etc.) only once; no checking to be sure that letters and words are correct.

- **No more repeating:** No more rereading books. No staring repeatedly at items to ensure that nothing is lost.

- **No more saving.** Throw tissues away immediately after using. Discard trash and junk mail immediately. Do not look into the trash can for lost items.

Phillip’s parents also were asked to stop reassuring him and to discontinue doing rituals for him. This was a very difficult session for Phillip and his family, but they understood the logic of ERP, and they were willing to try anything.

For the next 3 weeks, Phillip and his therapist met three times a week to conduct in vivo exposure sessions that helped him to face his core fears. For many of these sessions, Phillip was asked to bring hoarded items from home and to discard all unnecessary items during the therapy session. At first, this created tremendous anxiety, but over time, Phillip was able to throw things away with less fear of losing something important. He also developed the ability to conduct self-directed exposure at home. Other exposure sessions involved writing letters and mailing them without checking, reading passages from magazines and books only once, and sorting through junk mail to make quick decisions about what to save or discard. As Phillip was able
to take on more responsibility for home-based exposure, session frequency decreased
to two times per week, and then to once per week. After 3 months of treatment,
Phillip’s scores on the YBOCS (Yale-Brown Obsessive-Compulsive Scale) and BDI (Beck
Depression Inventory) had decreased to 20 and 19, respectively, demonstrating
significant improvement in obsessive-compulsive symptoms and depression. His SPAI
(Social Phobia and Anxiety Inventory) score, however, remained relatively
unchanged, suggesting that he was still experiencing significant social anxiety.

Next, while Phillip worked on maintaining the gains he had made following ERP, he
and his therapist conducted some role plays to evaluate his social skills. It was
apparent that Phillip had extreme difficulty with initiating and maintaining
conversations. His eye contact also was quite poor in social interactions. Thus, the
therapist devised a plan for teaching and practicing new skills, which also involved
additional exposure to Phillip’s core fears as he was asked to resume contact with old
friends and identify activities where he could meet new people. He practiced new
behaviors first in session with his therapist and then developed a hierarchy of feared
social situations in which he could practice his new behaviors. These practice exercises
also involved a form of exposure as Phillip was asked to make social contact, which
produced fears of negative evaluation. After another 3 months of treatment focused
on social skills training (and associated exposure), Phillip’s scores on the YBOCS and
BDI had decreased further (YBOCS = 15; BDI = 13), and his SPAI score had decreased
to 100. Phillip had gone back to school to take one class, he was spending small
amounts of time with old friends, and he was volunteering a few hours each week at
his church. (Courtesy of M. A. Stanley, Ph.D., and D. C. Beidel, Ph.D.)

AVERSION THERAPY
When a noxious stimulus (punishment) is presented immediately after a specific
behavioral response, theoretically, the response is eventually inhibited and extinguished.
Many types of noxious stimuli are used: electric shocks, substances that induce vomiting,
corporal punishment, and social disapproval. The negative stimulus is paired with the
behavior, which is thereby suppressed. The unwanted behavior may disappear after a
series of such sequences. Aversion therapy has been used for alcohol abuse, paraphilias,
and other behaviors with impulsive or compulsive qualities, but this therapy is
controversial for many reasons. For example, punishment does not always lead to the
expected decreased response and can sometimes be positively reinforcing. Aversion
therapy has been used with good effect in some cultures in the treatment of opioid
addicts (Fig. 28.8-1).
FIGURE 28.8-1
Treatment of addicts at Tham Krabok Monastery in Thailand results in a 70 percent success rate, according to its records. The 10-day free treatment begins with a vow to Buddha never to use narcotics again. Then, patients are given an herbal medicine that makes them vomit immediately. (From White PT, Raymer S. The poppy—for good and evil. *National Geographic.* 1985;167:187, with permission.)

EYE MOVEMENT DESENSITIZATION AND REPROCESSING
Saccadic eye movements are rapid oscillations of the eyes that occur when a person tracks an object that is moved back and forth across the line of vision. A few studies have demonstrated that inducing saccades while a person is imagining or thinking about an anxiety-producing event can yield a positive thought or image that results in decreased anxiety. Eye movement desensitization and reprocessing has been used in posttraumatic stress disorders and phobias.

POSITIVE REINFORCEMENT
When a behavioral response is followed by a generally rewarding event, such as food, avoidance of pain, or praise, it tends to be strengthened and to occur more frequently than before the reward. This principle has been applied in a variety of situations. On inpatient hospital wards, patients with mental disorders receive a reward for performing a desired behavior, such as tokens that they can use to purchase luxury items or certain privileges. The process, known as *token economy*, has successfully altered behavior. *Table 28.8-3* gives a summary of some clinical applications of behavior
Charles was a 70-year-old retired business executive. Throughout his life, his work consumed him. Although he married and had a family, his job was his primary focus. He went to the office early and came home late. He enjoyed what he did—it was stimulating and made him feel important and useful. But as he got older, his performance was not what it used to be, and he decided it was time to retire. However, his mood was pretty low when he no longer had a job. He did not have the energy to get more involved in his church or to develop other hobbies, so he sat around all day, without any social contacts. His wife and best friend encouraged him to go talk to someone. The therapist suggested that they try behavioral activation. Charles was somewhat skeptical, as it seemed too simple, but he needed to do something. The therapist spent some time with Charles talking about the kinds of activities that used to make him feel good and some of the things he used to enjoy. They then put together a list of things he might be able do—even if he did not feel much like it—just to see what would happen. The list included looking for volunteer work where he could use his job skills, spending more time with his wife in some of the activities they once had enjoyed (e.g., watching movies, taking walks), and rejuvenating an old hobby from his college days—fishing. Charles initially agreed to do some easy activities—go to one movie a week, take one walk a week, and contact his church activity leader about possible volunteer activities. He was surprised to find that even these “baby steps” helped him feel better. He had the chance to talk with
RESULTS

Behavior therapy has been used successfully for a variety of disorders (Table 28.8-3) and can be easily taught (Table 28.8-4). It requires less time than other therapies and is less expensive to administer. Although useful for circumscribed behavioral symptoms, the method cannot be used to treat global areas of dysfunction (e.g., neurotic conflicts, personality disorders). Controversy continues between behaviorists and psychoanalysts, which is epitomized by Eysenck’s statement: “Learning theory regards neurotic symptoms as simply learned habits; there is no neurosis underlying the symptoms, but merely the symptom itself. Get rid of the symptom and you have eliminated the neurosis.” Analytically oriented theorists have criticized behavior therapy by noting that simple symptom removal can lead to symptom substitution: When symptoms are not viewed as consequences of inner conflicts and the core cause of the symptoms is not addressed or altered, the result is the production of new symptoms. Whether this occurs remains open to question, however.

(Courtesy of Robert Paul Liberman, M.D., and Jeffrey Bedell, Ph.D.)
Behavioral medicine uses the concepts and methods described above to treat a variety of physical diseases. Emphasis is placed on the role of stress and its influence on the body, particularly on the endocrine system. Attempts to relieve stress are made with the expectation that either the disease state will lessen or the patient’s ability to tolerate the disease state will strengthen.

One study measured the effects of a behavioral medicine program on symptoms of acquired immunodeficiency syndrome (AIDS). The treatment group received training in biofeedback, guided imagery, and hypnosis. Results included significant decreases in fever, fatigue, pain, headache, nausea, and insomnia and increased vigor and hardiness.

Another study of immunological and psychological outcomes of a stress reduction program was conducted with patients with malignant melanoma. Results included significant increases in large granular lymphocytes (defined as CD57 with Leu-7) and natural killer (NK) cells (defined as CD16 with Leu-II and CD56 with NKH1), along with indications of increased NK cytotoxic activity. Also noted were significantly lower levels of psychological distress and higher levels of positive coping methods in comparison with patients who were not part of the group.

Many other applications of behavior therapy are used in medical care. In general, most patients feel they benefit from such interventions, especially in their ability to cope with chronic illness.

28.9 Hypnosis

The concept of hypnosis conjures up myriad perceptions among clinicians and the lay public. Even the term *hypnosis* can be misleading, coming as it does from the Greek root *hypnos* (meaning “sleep”). In reality, hypnosis is not sleep. It is more likely a complex process that requires alert focused and receptive attention. Hypnosis is a powerful means of directing innate capabilities of imagination, imagery, and attention. Many also believe the myth that the clinician projects the hypnotic trance onto the patient or has the power to influence the patient. In reality it is the patient who has the hypnotic gift, and the clinician’s role is to assess the patient’s capacity to capitalize on this asset and to help the patient discover and use it effectively. Patient motivation, personality style, and biological predisposition may contribute to the manifestation of this talent.

During the hypnotic trance, focal attention and imagination are enhanced and simultaneously peripheral awareness is decreased. This trance may be induced by a hypnotist through formalized induction procedures, but it can also occur spontaneously. The capacity to be hypnotized and, relatedly, the occurrence of spontaneous trance states is a trait that varies among individuals but is relatively stable throughout a person’s life cycle.

**HISTORY**

Descriptions of trance states, ecstatic states, and spontaneous dissociative states abound in the Eastern and Western religious, literary, and philosophical traditions. Anton Franz Anton Mesmer (1734–1815) first formally described hypnosis as a therapeutic modality in the 18th century and believed it to be the result of a magnetic energy or an invisible fluid that the therapist channels into the patient to correct imbalances, restoring health. James Braid (1795–1860), an English physician and surgeon, used eye fixation and closure to induce trance states. Later, Jean Martin Charcot (1825–1893) theorized the hypnotic state to be a neurophysiologic phenomenon that was a sign of mental illness. Contemporaneously, Hippolyte Bernheim (1840–1919) believed it to be a function of the normal brain.

Early in his career, Sigmund Freud (1856–1939) used hypnosis as part of his psychoanalysis and noticed that patients in a trance could relive traumatic events, a process called *abreaction*. Later, Freud switched from hypnosis to free association because he wanted to minimize the transference that sometimes accompanies the trance.
state. Importantly, the switch did not eliminate the occurrence of spontaneous trance during the analysis.

World War I produced many shell-shocked soldiers and Ernst Simmel (1882–1947), a German psychoanalyst, developed a technique for accessing repressed material that he named hypnoanalysis. During World War II, hypnosis played a prominent role in the treatment of pain, combat fatigue, and neurosis. Formal recognition of hypnosis as a therapeutic modality did not occur, however, until the 1950s. The British Medical Society recommended its teaching in medical schools in 1955 and the American Medical Association and American Psychiatric Association officially stated its safety and efficacy in 1958.

DEFINITION

Hypnosis is currently understood as a normal activity of a normal mind through which attention is more focused, critical judgment is partially suspended, and peripheral awareness is diminished. The trance state, being a function of the subject’s mind, cannot be forcibly projected by an outside person. The hypnotist, however, may aid in the achievement of the state and use its uncritical, intense focus to facilitate the acceptance of new thoughts and feelings, thereby accelerating therapeutic change. For the subject, hypnosis is typified by a feeling of involuntariness and movements seem automatic.

TRAIT OF HYPNOTIZABILITY

A person’s degree of hypnotizability is a trait that is relatively stable throughout the life cycle and is measurable. The process of hypnosis takes the hypnotizability trait and transforms it into the hypnotized state. Experiencing the hypnotic concentration state requires a convergence of three essential components: absorption, dissociation, and suggestibility.

Absorption is an ability to reduce peripheral awareness that results in a greater focal attention. It can be metaphorically described as a psychological zoom lens that increases attention to the given thought or emotion to the increasing exclusion of all context, even including orientation to time and space.

Dissociation is the separating out from consciousness elements of the patient’s identity, perception, memory, or motor response as the hypnotic experience deepens. The result is that components of self-awareness, time, perception, and physical activity can occur without being known to the patient’s consciousness and so may seem involuntary.

Suggestibility is the tendency of the hypnotized patient to accept signals and information with a relative suspension of normal critical judgment; it is controversial whether critical judgment can be completely suspended. This trait will vary from an almost compulsive response to input in the highly hypnotizable to a sense of automaticity in the less hypnotizable individual. Table 28.9-1 lists the indicators of trance development.
Indicators of Trance Development

- Autonomous ideation
- Balanced tonicity (catalepsy)
- Changed voice quality
- Comfort, relaxation
- Economy of movement
- Eye changes/closure
- Facial features ironed out
- Feeling distant
- Feeling good after trance
- Lack of body movement
- Lack of startle response
- Literalism
- Objective and impersonal ideation
- Pupillary changes
- Response attentiveness
- Retardation of reflexes:
  - Swallowing
  - Blinking
- Sensory, muscular, and body changes
- Slowing pulse
- Slowing and loss of blink reflex
- Slowing respiration
- Spontaneous hypnotic phenomena:
  - Amnesia
  - Anesthesia
  - Catalepsy
  - Regression
  - Time distortion
  - Time lag in motor and conceptual behavior

(From Erickson M, Rossi EL, Rossi SI. Hypnotic Realities: The Induction of Clinical Hypnosis and Forms of Indirect Suggestion. New York: Irvington; 1976:98, with permission.)

QUANTIFICATION OF HYPNOTIZABILITY

Quantifying a patient’s degree of hypnotizability is useful in a clinical setting because it predicts the effectiveness of hypnosis as a therapeutic modality. Quantification also provides useful information about the way patients relate to themselves and the social environment. Highly hypnotizable patients have an increased incidence of spontaneous trance-like states and so may be unduly influenced by ideas and emotions that are not being appropriately self-critiqued.

NEUROPHYSIOLOGICAL CORRELATES OF HYPNOSIS

Neurological testing of individuals in the hypnotized state and those with a high degree of hypnotizability has led to some interesting findings, but no set of changes has been shown to be sensitive or specific for the trance state or hypnotizability trait.

Electroencephalographic (EEG) studies have shown that hypnotized persons exhibit electrical patterns that are similar to those of fully awake and attentive persons and not like those found during sleep. Increased alpha activity and theta power in the left frontal region has been reported in highly hypnotizable patients as compared with those who are less hypnotizable; these differences exist in the trance and nontrance states.
Positron emission tomography (PET) studies that compare regional blood flow in the brain in both hypnotized and nonhypnotized subjects lend further evidence to the hypothesis that hypnosis exerts some of its effects at lower-level modalities of the brain. Hypnotic suggestions to add color to a visual image result in increased blood flow to the lingual and fusiform gyri, the color vision processing centers of the brain; suggestions to remove color have the opposite effect. Similarly, the intensity and noxiousness of pain are believed to be processed by different regions of the brain, because different areas of reduced blood flow result when each is minimized through hypnosis.

The role of the anterior brain regions, such as the frontal lobes, in hypnosis has been shown physiologically by the positive correlation between homovanillic acid concentrations in the cerebrospinal fluid and degree of hypnotizability. The frontal cortex and basal ganglia have a large number of neurons that use dopamine, of which the metabolite is homovanillic acid. This may explain why pharmacological enhancement of hypnotizability, although difficult, is primarily accomplished with dopaminergic agents, such as amphetamine. The increased activation of the basal ganglia may relate to the increased automaticity of hypnotic motor behavior.

**CLINICAL ASSESSMENT OF HYPNOTIC CAPACITY**

Two major procedures exist to clinically evaluate hypnotic capacity: the Stanford Hypnotic Susceptibility Scale and the Hypnotic Induction Profile (HIP) (Table 28.9-2). The Stanford Hypnotic Susceptibility Scale is a long laboratory-based test that has been modified for clinical evaluation and requires approximately 20 minutes to perform. It primarily measures behavioral compliance and suggestibility. The HIP is a shorter test that uses the eye-roll sign as a biological indicator and measures cognitive flow, which differentiates those with no hypnotic capacity because of mental pathology from those mentally normal patients with any inherent hypnotic capacity (Fig. 28.9-1).

**FIGURE 28.9-1**
Administration of the Hypnotic Induction Profile can be a routine part of the initial visit.
and evaluation. The test begins with the eye-roll sign, a presumptive measure of biological ability to experience dissociation. In the test procedure for eye-roll sign measurement, the patient is told “Hold your head looking straight forward; while holding your head in that position, look upward, toward your eyebrows—now toward the top of your head [up-gaze]. While continuing to look upward, close your eyelids slowly [roll].” The up-gaze and roll are scored on a 0 to 4 scale by observing the amount of sclera visible between the lower eyelid and the lower edge of the cornea. If an internal squint occurs, the degree is scored on a 1 to 3 scale. The squint score is added to the roll score. This procedure takes about 5 seconds. The eye-roll is a part of the hypnotic induction, which is also scored as an initial indicator of the potential for hypnotic experience. (Courtesy of Herbert Spiegel, M.D., Marcia Greenleaf, Ph.D., and Davig Spiegel, M.D.)

Table 28.9-2
Hypnotic Induction Profile–Derived Method of Self-Hypnosis

One, look up toward your eyebrows, all the way up; two, close your eyelids slowly and take a deep breath; count to three, exhale, let your eyes relax, and let your body float.

As you feel yourself floating, you permit one hand or the other to feel like a buoyant balloon and allow it to float upward. As it does, your elbow bends, and your forearm floats into an upright position. When your hand reaches this upright position, it becomes a signal for you to enter a state of meditation and to increase your receptivity to new thoughts and feelings.

In this state of meditation, you concentrate on this feeling of imaginary floating and, at the same time, concentrate on the following critical points (e.g., the three critical points to stop smoking in the following discussion).

Reflect on the implications of these critical points, and then bring yourself out of this state of concentration called self-hypnosis by counting backward in this manner: Three, get ready; two, with your eyelids closed, roll up your eyes (do it now); and, one, let your eyelids open slowly. Then, when your eyes are back in focus, slowly make a fist with the hand that is up; and, as you open your fist slowly, your usual sensation and control returns. Let your hand float down. That is the end of the exercise, but you can retain a general overall feeling of floating.

By doing this exercise ten different times each day, you can float into this state of buoyant repose. Give yourself this island of time, 20 seconds, ten times a day, in which to use this extra receptivity to reimpact these critical points. Reflect on them, then float back to your usual state of awareness, and then continue with what you ordinarily do.

(Courtesy of Herbert Spiegel, M.D., Marcia Greenleaf, Ph.D., and David Spiegel, M.D.)

INDUCTION

Many different induction protocols follow the same basic principles and pattern, but may be better suited to the patients with different levels of hypnotizability.

**Doctor:** Take a long, deep breath—inhale and exhale; now close your eyes and relax. Pay particular attention to the muscles in and about your eyes—relax them to the point that they just won’t work. Are you trying to do that? Good. If you really have
them relaxed, right at this very moment, no matter how hard you try, they just won’t open. Test them. The harder you try, the faster they stick together, just as if they were glued together. That’s fine!

Now you can open your eyes; that’s good. When I tell you to and not before, open and close your eyes once more, and, when you close them this time, you will be ten times as relaxed as you are right now. Go ahead, open and close, and feel that surge of relaxation go through your whole body, from the top of your head to the tip of your toes. Very good!

Now once again, open and close your eyes, and this time, when you close them, you will double the relaxation that you now have. Fine.

If you have followed my suggestions, right at this very moment, when I lift your hand and let it drop into your lap, it will drop like a wet cloth, heavy and limp. That’s very, very good.

You now have good physical relaxation, but medical relaxation consists of two phases: physical, which you now have, and mental, which I will now show you how to achieve.

When I ask you to and not before, I want you to start counting backward from 100. I know you can count; that is not what we’re after. I just want you to relax mentally. As you say each number, pause momentarily until you feel a wave of relaxation cover your whole body, from the top of your head to the tip of your toes. When you feel this wave of relaxation, then say the next number, and each time you say a number, you will double the relaxation you had before you said the number. If you do this properly, an interesting thing will happen—as you say the numbers and relax, the succeeding numbers will start to disappear and vanish from your mind. Command your mind to dispel these numbers. Now, aloud and slowly, start counting backward from 100.

Patient: One hundred.
Doctor: Very good.
Patient: Ninety-nine.
Doctor: Make them start to disappear now.
Patient: Ninety-eight.
Doctor: Now they’re fading away, and after the next number they’ll all be gone. Make them disappear. Let the numbers go.
Patient: Ninety-seven.
Doctor: And now they’re all gone. Are they gone? Fine. If there are any numbers still lurking in your mind, when I lift your hand and drop it, they will all disappear. (Courtesy of William Holt, M.D.)

INDICATIONS

A patient’s degree of hypnotizability and the technique of hypnosis are clinically useful in diagnosis and in treatment, respectively.
The existence of spontaneous, trance-like states in everyday life and the potential of individuals to uncritically accept emotions and information in these states make a person’s degree of hypnotizability a factor in the way the world is viewed and processed. A relation is seen between various conditions and hypnotizability. For example, patients with paranoid personality disorder are low and patients who are histrionic are higher on the hypnotizability spectrum. Patients with dissociative identity disorder are highly hypnotizable. Patients with eating disorders are difficult to hypnotize.

A 32-year-old man presented to the emergency department with a severe headache. He was a chronic migraine sufferer and had been unable to control the pain on this occasion with his propranolol (Inderal). The emergency department recognized that he had high hypnotic capacity. The imagery of an icepack being placed on his forehead was suggested. Initially some real ice was placed on his forehead to help. The patient was able to control his pain completely with this imagery. He did not require narcotics, as he had on previous visits. On follow-up several weeks later the patient reported being able to use this strategy to control, as well as prevent, migraine attacks, and he no longer had to rely on frequent emergency department visits for pain relief. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

A 22-year-old male patient was brought to the emergency room with bilateral blindness. Following an evaluation by ophthalmology, it was determined that the blindness was psychogenic. After initial evaluation by psychiatry, a therapeutic alliance was developed, and hypnosis was used to take the patient to a safe place and then back to the time immediately prior to the blindness. After two sessions the patient was able to describe seeing his wife in an adulterous relationship. At that moment the patient vocalized a desire to harm his wife and her suitor. Immediately after this vocalization, he became amnesic for the event and blind. On describing this under hypnosis, he was given a suggestion that when he became alert “He would only remember what he felt comfortable remembering.” Subsequent to the patient becoming alert, he had no idea what had occurred, and each day after the hypnotic intervention was initiated the patient’s anger was reframed. When the patient felt comfortable he then confronted his wife. The patient became aware that the amnesia was being used to prevent him from acting out. Use of a psychodynamic, cognitive reframing approach with a hypnotic milieu helped this patient to gain control and understanding of his symptoms. The patient and his wife were then referred for marital counseling. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

Therapeutically, hypnosis’s effectiveness in facilitating acceptance of new thoughts and feelings makes it useful in treating habitual problems and also with symptom management. Smoking, overeating, phobias, anxiety, conversion symptoms, and chronic
pain are all indications for hypnosis. They can often be treated in a single session, in which a patient is taught to perform self-hypnosis. Hypnosis can also aid in psychotherapy, notably for posttraumatic stress disorder, and it has been used for memory retrieval.

A 29-year-old woman was referred for evaluation and treatment of ongoing facial pain that was not responding to traditional methods of intervention. Neurological evaluation showed no objective physical correlations. Her high midrange performance on the HIP added support to the potential of a psychological mechanism for the pain. Initially the pain was controlled by a hypnotic intervention, but it returned 24 hours later. Her self-hypnotic technique ceased to be effective. A decision was made to explore more completely the meaning of the pain. Age regression under hypnosis was used, and the patient was regressed to a time prior to the pain. She related that her brother had been injured by a car while he was running in the street. The patient was babysitting at the time, and her father was so angered that he hit her. Recently her friend's dog ran away, and she felt responsible. As she began to recognize her need to punish herself because of her guilt over what had occurred, she was able to understand her feelings and reframe her thoughts in a more productive manner. An “affect bridge” was also used, and the patient was asked to go to back to a previous time when she felt guilty and was punished. She then was able to describe her feelings of being hit by her alcoholic, abusive father. She continued to gain insight and mastery over the past and was able to ablate her pain. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

A 42-year-old married mother of three children had been kidnapped and locked in a large packing trunk. After she had freed herself and broken out, her abductors had stabbed her multiple times, tied her up, put her back in the trunk, and thrown her down a cliff. She had eventually managed to break out and crawl to safety. Eventually she had been picked up by a passerby. She reported that others had seen her lying on the road and appeared frightened to approach her. Eventually 911 had been called and she had been transported to a hospital. Following medical stabilization she had been discharged and found herself developing nightmares, reexperiencing avoidance, and having hyperarousal symptoms. She was referred by her internist for treatment and was initially started on 25 mg of sertraline (Zoloft), which was increased to 50 mg 4 days later. She was evaluated on the HIP and determined to be a mid- to high-range hypnotic subject. She was taught to go to a safe place and to use a split-screen technique. She was also given permission to describe her nightmares, reexperiences, and overwhelming anxieties and fears that she faced while being captive, as well as her feelings of abandonment while lying on the road. She was reinforced for her ingenuity in breaking out of the trunk. Her feeling of blame for her capture was reframed while she was under hypnosis. She was taught to calm herself and to reframe her negative feelings about her helplessness. Hypnotic age regression was used to help her master her experiences and facilitate their
becoming like a bad movie. Initially her startle response was used as a signal for her to go to her comfort zone. Age progression was used to help her to rehearse the future. The treatment used the milieu of hypnosis along with exposure, cognitive reframing, psychodynamic approaches, and pharmacology. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

CONTRAINDICATIONS

No intrinsic dangers to the hypnotic process exist. Because of the increased dependence that the hypnotized patient has toward the therapist, a strong transference may occur, however, in which the patient exhibits feelings for the therapist that are inappropriate in regards to their relationship. Strong attachments may occur, and it is important that these are respected and properly interpreted. Negative emotions may also be brought out in the patient, especially those who are emotionally fragile or who have poor reality testing. To minimize the likelihood of this negative transference, caution should be taken when choosing patients who have problems with basic trust, such as those who are paranoid or who require high levels of control. The hypnotized patient also has a reduced ability to critically evaluate hypnotic suggestions and, thus, the hypnotist must have a strong ethical value system. Controversy exists about whether patients can perform acts during a trance state that they would otherwise find repugnant or that run contrary to their moral system.

REFERENCES

28.10 Interpersonal Therapy

Interpersonal psychotherapy (ITP), a time-limited treatment for major depressive disorder, was developed in the 1970s, defined in a manual, and tested in randomized clinical trials by Gerald L. Klerman and Myrna Weissman. ITP was initially formulated as an attempt to represent the current practice of psychotherapy for depression. It assumes that the development and maintenance of some psychiatric illnesses occur in a social and interpersonal context and that the onset, response to treatment, and outcomes are influenced by the interpersonal relations between the patient and significant others. The overall goal of ITP is to reduce or eliminate psychiatric symptoms by improving the quality of the patient’s current interpersonal relations and social functioning.

The typical course of ITP lasts 12 to 20 sessions over a 4-month to 5-month period. ITP moves through three defined phases: (1) The initial phase is dedicated to identifying the problem area that will be the target for treatment; (2) the intermediate phase is devoted to working on the target problem area(s); and (3) the termination phase is focused on consolidating gains made during treatment and preparing the patients for future work on their own (*Table 28.10-1*).

<table>
<thead>
<tr>
<th>Phases of Interpersonal Psychotherapy</th>
</tr>
</thead>
</table>

*Table 28.10-1*
Individual Interpersonal Psychotherapy

Initial Phase. Sessions 1 through 5 typically constitute the initial phase of ITP. After assessing the patient’s current psychiatric symptoms and obtaining a history of these symptoms, the therapist gives the patient a formal diagnosis. Therapist and patient then discuss the diagnosis, as well as what might be expected from treatment. Assignment of the sick role during this phase serves the dual function of granting the patient both the permission to recover and the responsibility to recover. The therapist explains the rationale of ITP, underscoring that therapy will focus on identifying and altering dysfunctional interpersonal patterns related to psychiatric symptomatology. To determine the precise focus of treatment, the therapist conducts an interpersonal inventory with the patient and develops an interpersonal formulation based on this. In the interpersonal formulation, the therapist links the patient’s psychiatric symptomatology to one of the four interpersonal problem areas—grief, interpersonal deficits, interpersonal role disputes, or role transitions. The patient’s concurrence with the therapist’s identification of the problem area and agreement to work on this area are essential before beginning the intermediate treatment phase.
Intermediate Phase. The intermediate phase—typically sessions 6 to 15—constitutes the “work” of the therapy. An essential task throughout the intermediate phase is to strengthen the connections the patient makes between the changes he or she is making in his or her interpersonal life and the changes in his or her psychiatric symptoms. During the intermediate phase, the therapist implements the treatment strategies specific to the identified problem area as specified in Table 28.10-2.

Termination Phase. In the termination phase (usually, sessions 16 through 20), the therapist discusses termination explicitly with the patient and assists him or her in understanding that the end of treatment is a potential time of grief. During this phase, patients are encouraged to describe specific changes in their psychiatric symptoms, especially as they relate to improvements in the identified problem area(s). The therapist also assists the patient in evaluating and consolidating gains, detailing plans for maintaining improvements in the identified interpersonal problem area(s), and outlining remaining work for the patient to continue on his or her own. Patients are also encouraged to identify early warning signs of symptom recurrence and to identify plans of action.

Ms. G is a 51-year-old woman who presented for treatment of binge eating disorder. She is college educated, has her own business, and is a divorced mother of one adult son in his early 20s. Before treatment, she had a body mass index (BMI) of 42 and had been binge eating approximately 10 to 15 days per month for the past 8 years. Along with her current diagnosis of binge eating disorder, Ms. G struggled with recurrent major depression.

During the initial phase, Ms. G and her therapist began to review her history and the interpersonal events that were associated with her binge eating. Ms. G shared that she began overeating and gaining weight at age 14. When she was 18 years of age,
she moved to a foreign country with her parents. Soon after the move, Ms. G’s father left her and her mother to return to the United States. Ms. G was enraged at her father for leaving them and still gets very tearful and angry when discussing the separation. She and her mother decided to stay abroad because she had started university and her mother was working. Both had developed strong social ties and felt comfortable in their new home. During this time, Ms. G continued to gain weight and started dieting. Shortly after graduating from university, Ms. G met and married a foreign national and, at the age of 28, delivered their only son. Two years later, she and her husband went through a very bitter divorce. Although Ms. G described this as a terrible time in her life, she maintained close ties with her friends and her mother. During this time, she began to diet and reached her lowest adult weight. At the age of 35, when her mother died of a heart condition, Ms. G had her first episode of major depression, which was treated and resolved with antidepressants and a brief course of psychotherapy. Although she had previous cycles of weight loss and weight regain, she did not evidence any sign of eating disturbance at this point. She continued to maintain close social ties and enjoyed her close relationship with her son. When Ms. G was in her early 40s, an economic downturn in her adopted country forced her to return to the United States. Having lost all of her savings, she struggled financially while she looked for work. During this time, she started binge eating and gaining weight. Within 1 year of this move, Ms. G’s son decided to return to live with his father (who was very wealthy). Ms. G felt angry and betrayed. Yet, when her son would visit, she would assume a subservient role with him, because she was afraid of losing his affection. He, in turn, became quite demanding and critical of her. Before seeking treatment, her heightened feelings of isolation and loneliness were leading to increased binge eating, depression, and weight gain.

By session 3 of the initial phase, Ms. G’s therapist began to consider which problem area would be the focus of the remainder of treatment. Ms. G had a history of important relationship losses and subsequent grief—the loss of her father, her husband, her mother, and, most recently, her son. However, none of these losses was associated with the development of binge eating problems (although her dieting was clearly linked to her feelings of anger after the divorce from her husband and her depression was intimately linked with her mother’s death). Ms. G’s anger at her son for returning to live with the enemy was clearly a role dispute, yet her binge eating had begun 2 years before his departure (although it clearly worsened after he left). Because neither of these problem areas was directly linked to the onset of the eating disorder, Ms. G’s therapist decided that the focus of treatment would be to assist her in managing her role transition. Her move back to the United States, with the subsequent loss of her support and friendship networks, was clearly associated with the onset and continued maintenance of her binge eating. During session 4 of the initial phase, Ms. G’s therapist shared her formulation of the problem area with her: “From what you have described, your binge eating really began after you returned to the United States. After that transition, you were more isolated and alone than you have ever been. It seems that binge eating was a way for you to manage that
transition and the subsequent feelings of isolation and loneliness. Your transition has also had a negative impact on your relationship with your son. Even though you are a very social person and enjoy the company of others, you have yet to develop the kind of support that you had before you moved. Although you have struggled with some very significant issues over the course of your life—your father leaving, the pain of the divorce, and the death of your mother—your friends and support systems sustained you. If we work together to help you find and develop more intimate and supportive relationships here, I believe you will be much less likely to turn to food and binge eating as a source of support or comfort.”

Ms. G agreed with the formulation and worked with her therapist to establish some treatment goals to help her resolve the problem area. First, she was encouraged to become more aware of her feelings (especially isolation and loneliness) when she was binge eating and of how binge eating seemed to be the way she managed those feelings. A second goal was for her to take steps to increase her social contacts and develop more friendships. The third goal, which was identified as a secondary problem area, centered on helping Ms. G resolve the role dispute with her son. Specifically, the therapist developed a goal with her to help her establish a clearer parental role with her son.

During the intermediate phase, the therapist helped Ms. G grieve the loss of her previous role and the extensive support that she once had. Ms. G and her therapist worked to identify several sources of support and friendships of which she had not been aware. Soon after, Ms. G reported significant progress in initiating and establishing relationships with others. This change appeared to help give her confidence in her new roles. In fact, she had begun to receive a few social invitations. She was more attuned to the ways that she would rely on food, especially when she felt lonely or felt that she was not receiving enough time from others. The connection between the lack of supportive contacts and binge eating was becoming very clear to her in these intermediate sessions. During this phase, the therapist also assisted her in setting appropriate limits in her relationship with her adult son and in recognizing his adult-like responses in return. By the termination phase, Ms. G reported that she no longer felt so lonely and isolated and that her binge eating had all but disappeared. She remarked how the quality of her relationship with her son had changed dramatically. He was more supportive and respectful, visited more frequently, and stayed with her for longer periods of time. In the final sessions, she talked about her need to let go of the past and move on with her life as it is now, assuming her new roles more fully. She worked closely with her therapist to develop a plan to maintain the gains that she had made in treatment and used the final session to review the important work that she had accomplished. (Courtesy of D. E. Wilfley, Ph.D., and R. W. Guynn, M.D.)
A recent approach in the ongoing development of ITP has been its use in a group format. ITP delivered in a group format has many potential benefits in comparison with individual treatment. For example, a group format in which membership is based on diagnostic similarity (e.g., depression, social phobia, eating disorders) can help alleviate patients’ concerns that they are the only one with a particular psychiatric disorder, while offering a social environment for patients who have become isolated, withdrawn, or disconnected from others. Given the number and different types of interpersonal interactions in a group setting, the interpersonal skills that are developed may be more readily transferable to the patient’s outside social life than are the relationship patterns that are addressed in a one-on-one setting. Moreover, a group modality has therapeutic features not present in individual psychotherapy (e.g., interpersonal learning). The group format also facilitates the identification of problems common to many patients and provides a cost-effective alternative to individual treatment. Table 28.10-3 links the phases of ITP to the stages of group development.

**Timeline and Structure of Treatment.** The typical course of group ITP lasts 20 sessions over a 5-month period. It is recommended that group size range from six to nine members, with one or two group leaders, depending on resources and training needs. The three individual meetings (pregroup, midgroup, and postgroup), sequenced to correspond with critical time points in the three phases of ITP, in combination with other techniques, were designed to maintain the exclusive and strategic focus on individual patients’ interpersonal problem areas—the hallmark of ITP.

**Pregroup Meeting.** The pretreatment meeting is crucial for facilitating a patient’s individualized work in the first phase of group ITP. The focus of the 2-hour pretreatment meeting is to identify interpersonal problem areas, establish an explicit treatment contract to work on problem areas, and prepare patients for group treatment. After identifying a patient’s interpersonal problem(s) (i.e., interpersonal deficits, role disputes, role transitions, or grief), the therapist works collaboratively with the patient to formulate concrete prescriptions for change, in addition to the specific steps the
The patient will take to improve social relationships and patterns of relating. These goals of treatment are expressed in language that is as specific and personally meaningful to the patient as possible. Before the start of the group, each group member is given a written summary of his or her goals and told that these goals will guide his or her work in the group.

Another important element of the pregroup meeting involves adequately preparing patients for group treatment. That is, patients are encouraged to think of the group as an “interpersonal laboratory” in which they can experiment with new approaches to handle challenging interpersonal situations. In this regard, patients are informed about the important interpersonal skills that are learned while participating in a group (e.g., interpersonal confrontation, honest communication, expression of feelings) and are encouraged to learn from others as they see changes occur. The therapist stresses to patients the importance of keeping their work in the group focused on changing their current interpersonal situations or intensifying important existing relationships and not using the group as a substitute social network.

**Initial Phase.** The first five sessions of the group treatment comprise the initial phase in group ITP. During this phase, the therapist works to cultivate positive group norms and group cohesion, while emphasizing the commonality of symptoms among members and how they will be addressed in the group context. During this phase, group members are encouraged to review their goals with the group and begin to make some initial changes in their respective interpersonal problem areas. As members begin to experiment with the changes outlined in their goals, the therapist works collaboratively with each group member to refine and make any alterations in the target areas before the beginning of the intermediate phase.

**Intermediate Phase.** During the intermediate “work” phase of group ITP (sessions 6 through 15), the therapist works to facilitate connections among members as they share the work on their goals with one another. In contrast to other interactive group approaches, the group interpersonal psychotherapist is much less likely to focus on intragroup processes and relationships unless they are specific to the work on a member’s interpersonal problem area (e.g., interpersonal deficits). The therapist, however, consistently and continuously encourages group members to practice newly acquired interpersonal skills both inside and, most importantly, outside the group. As is the case with individual ITP, an essential task throughout the intermediate phase is to strengthen the connections the group members make between difficulties in their interpersonal lives and their psychiatric problems.

**Midtreatment Meeting.** The midtreatment meeting is held midway (usually between sessions 10 and 11) through the intermediate phase. This meeting provides an opportunity to conduct a detailed review of each group member’s progress on his or her individual problems and to refine interpersonal goals. The therapist(s) recontracts with group members during this meeting as a means of outlining and emphasizing the work
that remains, both inside and outside of the group, before the conclusion of treatment.

**Termination Phase.** In the termination phase (sessions 16 through 20), the therapist discusses termination explicitly with the group members and begins to help them recognize that the end of treatment is a time of possible grief and loss. The therapist helps members recognize their own progress and the progress made by other group members. During this phase, group members are encouraged to describe the specific changes in their psychiatric symptoms, especially as they relate to improvements in the identified problem area(s) and relationships. Although it is common for group members to want to keep meeting on their own or to have frequent reunions, group members are encouraged to use this phase of the group to formally say goodbye to one another and to the therapist(s). The therapist(s) also uses this time to encourage members to detail their plans for maintaining improvements in their identified interpersonal problem area(s) and to outline their remaining work.

**POSTTREATMENT MEETING.** The posttreatment meeting is scheduled within 1 week after the final group session. The therapist(s) uses this final individual meeting to develop an individualized plan for each group member’s continued work on his or her interpersonal goals. The therapist(s) reviews the group experience and the changes the patient has made in his or her interpersonal problem area and significant relationships.

**28.11 Narrative Psychotherapy**
More than anything else psychiatrists do, they listen to stories. These stories so saturate
the clinical encounter that it would be impossible to imagine a clinical encounter
without them. In the very first meeting between psychiatrist and patient, the
psychiatrist begins with an open-ended invitation to a story: “What brings you here?” or
“What seems to be the problem?” Patients respond to these questions by telling
psychiatrists about their lives, their troubles, when the troubles began, what seems to
have caused them, how they create difficulty, and what kinds of problem solving they
have tried. Such stories may be rudimentary, they may be only partially worked out,
and they may even be baffled and confused. The patient may even be perplexed enough
to answer “I don’t know why I came” or “I’m not really sure what’s wrong, my family
sent me.” Nonetheless, the patient’s response to the psychiatrist’s initial questions
always involves a story.

Narrative psychotherapy emerges out of this increased interest in clinical stories. The
two main tributaries that lead to narrative psychotherapy come from the two different
sides of psychiatry: narrative medicine and narrative psychotherapy. Narrative
psychiatrists are psychiatrists who combine the wisdom of these two domains. Following
the lead of narrative medicine, narrative psychiatrists recognize that psychiatric
patients, like medical patients, come to clinics with intense stories to tell. Contemporary
narrative medicine has developed from 30 years of work in bioethics and medical
humanities devoted to humanizing the clinical encounter through a better understanding
of patient stories. The term narrative medicine comes from Rita Charon, an internist and
literary scholar, who used it to describe an approach to medicine that uses narrative
approaches to augment scientific understandings of illness. Narrative medicine brings
together insights from human-centered medical models, such as George Engel’s
biopsychosocial model and Eric Cassel’s person-centered model, with research and
insights from phenomenology, the humanities, and interpretive social sciences.

Narrative medicine uses these resources to better understand the illness experience,
“to recognize, absorb, interpret, and be moved by the stories of illness.” As Charon
argued, when clinicians possess narrative competency, they can enter the clinical setting
with a nuanced capacity for “attentive listening. . . , adopting alien perspectives,
following the narrative thread of the story of another, being curious about other
people’s motives and experiences, and tolerating the uncertainty of stories.” She further
argued that doctors “need rigorous and disciplined training” in narrative reading and
writing not just for their own sake (helping them to deal with the strains and traumas of
clinical work), but also “for the sake of their practice.” Without such narrative
competency, clinicians lack the ability to fully understand their client’s experience of
illness. For Charon and others in narrative medicine, narrative study is not a mere
adornment to a doctor’s medical training; it is a crucial and basic science that must be
mastered for medical practice.

A major task of narrative medicine, and therefore narrative psychotherapy, is to be a
good listener and to connect empathically with the patient’s story. A narrative
psychiatrist, like a narrative physician, seeks to understand the patient first and
foremost. This understanding brings patient and clinician together into a shared
experience of the patient’s world. This narrative understanding is much more than a causal explanation of problem A or problem B that the patient might have. It does not simply abstract from the person’s situation a categorical label that groups problems under a well-known abstract grid. Instead, narrative understanding tunes in to the uniqueness of the individual and the unrepeatability of the person’s experience and difficulties. Narrative understanding, in short, is a deep appreciation of the person as a whole—what it feels like for this person, in this particular context, going through these particular problems.

In addition to following the lead of narrative medicine colleagues, narrative psychiatrists also follow the lead of contemporary colleagues in narrative psychotherapy. The history of narrative psychotherapy goes back to Sigmund Freud’s early work at the inception of psychoanalysis. At that time, Freud lamented about how his case histories sounded more like narrative fictions than hard science.

Contemporary narrative psychotherapy’s motivation for returning to the role of narrative comes partly from the broader turn to narrative in humanities, psychology, and social science and partly from the history of psychotherapy since Freud. The past century of psychotherapy has been a century of strife, with one faction after another splitting off from psychoanalysis. Leading alternatives to psychoanalysis included behavioral, humanistic, family, cognitive, feminist, and interpersonal, just to name some. All of these splits are characterized by further splits within splits, which has fragmented the field of psychotherapy to the point that there are now more than 400 active approaches to psychotherapy. Narrative approaches emerge at this particular moment as part of an important trend away from further fragmentation and toward psychotherapy reintegration. Narrative approaches are invaluable for psychotherapy integration because they provide a metatheoretical orientation from which to understand and practice psychotherapy.

METAPHOR

Metaphor performs this function by allowing us to understand and experience one thing in terms of something else. The metaphor selects, accentuates, and backgrounds aspects of two systems of ideas so that they come to be seen as similar: “Men are seen to be more like wolves after the wolf metaphor is used, and wolves seem to be more human.”

Understanding metaphor in this way connects to broader work in continental linguistic philosophy, and that work, as a whole, shifts standard ideas about truth and objectivity. It allows us to sidestep the usual binary traps between relativism (anything goes) and realism (there is only one correct or true way to describe the world). When the role of language is understood as a mediator between our concepts and the world, it no longer makes sense to think in these highly modernist either/or terms. Rather than using the rigid binary distinction between true and false, it becomes possible to think instead in a postmodern language of semiotic realism and pluridimensional consequences.
**PLOT**

Plot works like metaphor in that it also orders experiences and provides form for narratives. Plot, or the process of emplotment, adds to metaphor two key dimensions: (1) it brings together what would otherwise be separate and heterogeneous elements, and (2) it organizes understanding and experience or time, or what could be called temporal perception.

The critical function of plot for narrative is that plot creates a narrative synthesis between multiple individual events and brings them together into a single story. It allows an intelligible connection to be made between them. Remarkably, plot can create a synthesis between events and elements that are surprisingly incongruous or heterogeneous—events that do not seem to fit together.

Plot also configures these multiple elements into a temporal order. This temporal order is of two sorts. First, each plot is comprises a discrete series of incidents, of theoretically infinite *nows*. Second, each plot takes these infinite nows, proceeding one after another in succession, and organizes them into a humanly manageable experience.

**CHARACTER**

In narrative theory, the concept of character connects directly to contemporary controversy surrounding the related and, some may argue, more basic concept of identity. The controversy around identity may be understood as a tension between essentialist and nonessentialist approaches. Essentialist notions of identity tell us that each person has a fixed personality, perhaps biologically stamped, that authentically belongs to that person and that is at the core of that person’s being. This “true self” or “core self” may be distorted or covered over, but it is nonetheless there for the discovery if individuals apply themselves patiently and persistently to the task. Nonessentialist critiques, however, have deconstructed this ideal of identity and its notion of an integral, originary, and unified self. One of the most productive ways to navigate the tension between essentialist and nonessentialist understandings of identity is to draw a comparison between identity (in life) and character (in fiction). Rather than adopting a linear logic that understands identity as a more fundamental concept to character, this approach uses a circular logic to argue that people understand themselves in the same way they understand characters.

Narrative approaches to identity allow people to navigate the tension between essentialist and nonessentialist identities because narrative identity allows for a kind of continuity over time, a relative stability of self, without implying a substantial or essentialist core to this stability. People’s interpretations of themselves use the cultural stories with which they are surrounded to tell a story of self that escapes the two poles of random change and absolute identity. In this way, a narrative identity is also a cultural identification. A person’s identification may seem original, but he or she narrates them with the resources of history, language, and culture.
With this brief introduction into narrative medicine, narrative psychotherapy, and narrative theory, it is possible to draw out further the meaning of narrative for psychiatry.

Fortunately, one of the most helpful aspects of narrative theory for psychiatry is that it provides an overarching, or metatheoretical, rationale for understanding how these many psychotherapies work. From a narrative perspective, all therapies involve a process of story telling and story retelling. No matter which style of psychotherapy one uses, the process of therapy involves an initial presentation of problems that the client is unable to resolve. The client and therapist work together to bring additional perspectives to these problems, allowing the client to understand them in a new way. These additional perspectives vary greatly depending on which style of psychotherapy is used. It matters, in other words, whether the therapy is psychodynamic, cognitive, humanistic, feminist, spiritual, or expressive. From the vantage point of narrative theory, however, what these different approaches all have in common is that they rework, or “re-author,” the patient’s initial story into a new story. This new story allows new degrees of flexibility for understanding the past and provides new strategies for moving into the future.

Recent work in narrative medicine, narrative psychotherapy, and narrative theory has opened the door for the development of narrative psychiatry. This development provides a critical corrective to contemporary psychiatric practice that helps to bring psychiatry back from its current obsessions with science and scientific method. This corrective is not a return to psychoanalysis nor does it demolish the progress of scientific psychiatry. When psychiatrists take a narrative turn, they do not throw out their other skills and knowledge. The shift to narrative is, as much as anything else, an attitude shift and an opening out to additional sources of information. It starts by bringing to the foreground that the clinical encounter is a human encounter, and it follows by opening out to colleagues in the humanities, interpretive social sciences, and the arts to help to better understand this human encounter.

Most of all, narrative psychotherapy joins with other contemporary efforts in psychiatry—such as the recovery movement—to make clinical encounters much more client focused and collaborative. Narrative psychotherapy, at its core, recognizes that there are many ways to tell the story of one’s life. The choice among these different options is a key way in which people create their identity. These choices should not be reduced to expert choices or scientific choices because they are always also personal and ethical choices. In the end, they are choices about what kind of life one wants to live. Furthermore, clinicians must come to understand the value of biography, autobiography, and literature for developing a repertoire of narrative frames and options. In the end, narrative competency in psychiatry means a tremendous familiarity
with the many possible stories of psychic pain and psychic difference. The more stories clinicians know, the more likely they are to help their clients to find a narrative frame that works for them.

For patients and potential service users, a narrative understanding means that there is a range of possible therapists and healing solutions that might be helpful. An approach that is right for one person may not be right for another. There must be a fit between the person and the approach, and people should feel empowered to take seriously their intuitions and feelings. If the person getting help does not feel this fit, he or she is likely right. There may well be another approach that would work better with the person’s proclivities. Like everything else, however, judgment is critical. Therapeutic experiences of all kinds can be frustrating, slow, and uncertain. How, for example, does one know when an approach misses his or her needs and when it is something that will take time, patience, and perseverance to be helpful? From a narrative perspective, there can be no gold standard or simple answers. Only judgment, wisdom, and trial and error can decide.

28.12 Psychiatric Rehabilitation
Psychiatric rehabilitation denotes a wide range of interventions designed to help people with disabilities caused by mental illness improve their functioning and quality of life by enabling them to acquire the skills and supports needed to be successful in usual adult roles and in the environments of their choice. Normative adult roles include living independently, attending school, working in competitive jobs, relating to family, having friends, and having intimate relationships. Psychiatric rehabilitation emphasizes independence rather than reliance on professionals, community integration rather than isolation in segregated settings for persons with disabilities, and patient preferences rather than professional goals.

**VOCATIONAL REHABILITATION**

Impairment of vocational role performance is a common complication related to schizophrenia. Studies across the United States show that less than 15 percent of patients with severe mental illnesses, such as schizophrenia, are employed. Nevertheless, studies also show that competitive employment is a primary goal for 50 to 75 percent of patients with schizophrenia. Because of patient interests and historical factors, vocational rehabilitation has always been a centerpiece of psychiatric rehabilitation.

Antonio is a 45-year-old man who has been a client of a mental health agency for more than 10 years. He attended the rehabilitative day treatment program until it was converted to a supported employment program. His case manager encouraged him to think about the possibility of working part time. Antonio told his case manager that he could not work because of his schizophrenia and because he was helping to raise his two kids and needed to be home at 3 P.M., when they returned from school every day. The case manager explained to Antonio that getting a job does not necessarily mean working 40 hours a week and that lots of people in the agency’s supported employment program were working in part-time jobs, even jobs that only require a few hours a week.

Antonio agreed to meet one of the employment specialists to discuss the possibility of work. Over the next couple of weeks, the employment specialist met with Antonio several times, read his clinical record, and talked with his case manager and psychiatrist. The employment specialist learned that Antonio loved to drive his car. He also learned that Antonio had attendance problems in past jobs because he felt unappreciated. The employment specialist found Antonio to be a sociable and likable person.

Antonio told the employment specialist that he was willing to do any job. He did not have one specific job in mind. After discussing options with Antonio and with the team, the employment specialist suggested a job at Meals on Wheels as a driver for the lunch delivery. Antonio was hired and loved it right from the start. Absenteeism was never a problem, because he liked driving around and knew that people were counting on him for their meals. The hours were perfect (10 A.M. to 2 P.M.), so he
could be at home when his kids returned from school. He became good friends with the other workers. He told his case manager that it was wonderful to be bringing home a paycheck again. And best of all, he said, was that his kids saw him going to work just like their friends’ dads. (Courtesy of Robert E. Drake, M.D., Ph.D., and Alan S. Bellack, Ph.D.)

**SOCIAL SKILLS REHABILITATION**

Social dysfunction is a defining characteristic of schizophrenia. People with the illness have difficulty fulfilling social roles, such as worker, spouse, and friend, and have difficulty meeting their needs when social interaction is required (e.g., negotiating with merchants, requesting assistance to solve problems). Social dysfunction is semi-independent of symptomatology and plays an important role in the course and outcome of the illness. As shown in **Table 28.12-1**, social competence is based on three component skills: (1) social perception, or receiving skills; (2) social cognition, or processing skills; and (3) behavioral response, or expressive skills. Social perception is the ability to read or decode social inputs accurately. This includes accurate detection of affect cues, such as facial expressions and nuances of voice, gesture, and body posture, as well as verbal content and contextual information. Social cognition involves effective analysis of the social stimulus, integration of current information with historical information, and planning an effective response. This domain is also referred to as *social problem solving*.

**Table 28.12-1**

Components of Social Skill
Methods

The primary modality of social skills training is role play of simulated conversations. The trainer first provides instructions on how to perform the skill and then models the behavior to demonstrate how it is performed. After identifying a relevant social situation in which the skill might be used, the patient engages in role play with the trainer. The trainer next provides feedback and positive reinforcement, which are followed by suggestions for how the response can be improved. The sequence of role play followed by feedback and reinforcement is repeated until the patient can perform the response adequately. Training is typically conducted in small groups (six to eight patients), in which case patients each practice role playing for three to four trials and provide feedback and reinforcement to one another. Teaching is tailored to the individual—for example, a highly impaired group member might simply practice saying “no” to a simple request, whereas a less cognitively impaired peer might learn to negotiate and compromise.

Richard was a single white man first diagnosed with schizophrenia at age 22, when he was a freshman at college. He was hospitalized briefly but was unable to return to school and moved back home with his parents. He attended a day treatment program intermittently over the next 6 years, before he was referred for help with getting a job and dating.

Richard had missed out on a critical period of adult development and had never learned dating skills or the social skills needed to get or maintain a job. He was
appropriately groomed and did not present himself as a patient, but he seemed quite uncomfortable in social interactions. He scarcely made eye contact, staring at the floor when he spoke, and did not initiate conversation, responding to questions with brief answers.

Richard was invited to participate in a social skills training group for 3 months with six other patients. The focus of the group was employment skills. Patients were taught critical social skills for getting and maintaining a job, such as how to participate in job interviews; how to approach a supervisor to understand how to do a job or for help with work-related problems; how and when to make requests or explain problems, such as getting to work late because of traffic or needing to leave early to go to a doctor’s appointment; and socializing with coworkers. Simultaneously, Richard was enrolled in a supported employment program and worked with a case manager to find a job as a computer support person. He found a 24-hour-per-week job at a small company and continued to attend the skills group, using the sessions to work on interpersonal issues at work, including engaging in casual conversation with coworkers and dealing with unreasonable requests from people.

When the vocational skills group ended, Richard was scheduled for a dating group with seven other male and female patients who had similar interests. This group focused on finding someone to date, dating etiquette, asking someone out (or being asked out), appropriate conversation for dates, sexual interactions, and safe sex practices. In addition to role play and discussion, the group shared ideas on how to meet people and what to do on dates.

Richard responded well to treatment. He had maintained the computer job at follow-up, 6 months after he concluded the dating skills group. His case manager also reported that he had a girlfriend, a woman whom he had met at his church group. He had also expressed an interest in enrolling in college classes at night. He was still living at home with his parents, but, for the first time, was seriously considering what he would need to do to move out. (Courtesy of Robert E. Drake, M.D., Ph.D., and Alan S. Bellack, Ph.D.)

Goals

In a treatment setting, there are four major goals of social skills training: (1) improved social skills in specific situations, (2) moderate generalization of acquired skills to similar situations, (3) acquisition or relearning of social and conversational skills, and (4) decreased social anxiety. Learning, however, is tedious or almost nonexistent when patients are floridly ill with positive symptoms and high levels of distractibility.

Some findings limit the applicability of social skills training. It is more difficult to teach complex conversational skills than to teach briefer, more discrete verbal and nonverbal responses in social situations. Because complex behaviors are more critical for generating social support in the community, methods have been developed to improve the learning and durability of conversational skills. These training methods, focusing on
Training in Social Perception Skills

Recently, efforts have been made to develop strategies for training patients in affect and social cue recognition. Patients with chronic psychotic disorders, such as schizophrenia, often have difficulty perceiving and interpreting the subtle affective and cognitive cues that are critical elements of communication. Social perception abilities are considered the first step in effective interpersonal problem solving; difficulties in this area are likely to lead to a cascade of deficits in social behavior. Training skills in social perception address these deficits and help provide a foundation for developing more specific social and coping skills.

Despite attending several social gatherings, Matt felt apart from the rest of the group. He reported that these events seemed like “a jumble of sights and sounds.” His therapist, recognizing Matt’s difficulty with social perception, gave him a series of questions designed to help him organize and give meaning to the social stimuli he encountered. For example, when Matt was confused about a conversation someone was having with him, he would ask himself, “What is this person’s short-term goal? At what level of disclosure should I be? Should I be talking now or listening?” Identifying the rules and goals of a particular social interaction provided a template for Matt to recognize, and react to, a greater variety of social cues, thus enhancing his behavioral repertoire. (Courtesy of Robert Paul Liberman, M.D., Alex Kopelowicz, M.D., and Thomas E. Smith, M.D.)

Information-Processing Model of Training. Methods of training that follow a cognitive perspective teach patients to use a set of generative rules that can be adapted for use in various situations. For example, a six-step problem-solving strategy has developed as an outline for helping patients overcome interpersonal dilemmas: (1) adopt a problem-solving attitude, (2) identify the problem, (3) brainstorm alternative solutions, (4) evaluate solutions and pick one to implement, (5) plan the implementation and carry it out, and (6) evaluate the efficacy of the effort and, if ineffective, choose another alternative. Although the step-wise, structured, linear process of problem solving occurs intuitively, without conscious awareness in normal persons, it can be a useful interpersonal crutch to help cognitively impaired mental patients cope with the information needed to fill their social and personal needs.

MILIEU THERAPY

The locus of milieu is a living, learning, or working environment. The defining characteristics of treatment are the use of a team to provide treatment and the time the patient spends in the environment. Recent adaptations of milieu therapy include 24-
hour-a-day programs situated in community locales frequented by patients, which provide in vivo support, case management, and training in living skills.

Most milieu therapy programs emphasize group and social interaction; rules and expectations are mediated by peer pressure for normalization of adaptation. When patients are viewed as responsible human beings, the patient role becomes blurred. Milieu therapy stresses a patient’s rights to goals and to have freedom of movement and informal relationship with staff; it also emphasizes interdisciplinary participation and goal-oriented, clear communication.

**Token Economy**

The use of tokens, points, or credits as secondary or generalized reinforcers can be seen as normalizing a mental hospital or day hospital environment with a program mimicking society’s use of money to meet instrumental needs. Token economies establish the rules and culture of a hospital inpatient unit or partial hospitalization program, offering coherence and consistency to the interdisciplinary team as it struggles to promote therapeutic progress in difficult patients. These programs are challenging to establish, however, and their widespread dissemination has suffered because of the organizational prerequisites and the additional resources and rewards needed to create a truly positively reinforcing environment. Table 28.12-2 lists behaviors that can be reinforced by tokens.

**Table 28.12-2**

*Contingencies of Reinforcement in the Token Economy Used at the Camarillo–UCLA Clinical Research Unit*

| Contingencies of Reinforcement in the Token Economy Used at the Camarillo–UCLA Clinical Research Unit | a |
Increased recognition of the prevalence and importance of neurocognitive deficits over the past decade has stimulated increasing interest in remediation strategies. Much of the work in this area has focused on psychopharmacological approaches, especially on the new-generation antipsychotics. New-generation medications appear to have a positive effect on neurocognitive test performance, but the effect size for any of the medications is small to medium, and little evidence indicates that these medications have a clinically meaningful impact on neurocognitive functioning in the community. As a result, a parallel interest has arisen in the potential for rehabilitation or cognitive remediation. This body of work is distinguished from cognitive-behavioral therapy and cognitive therapy, which focus on reducing psychotic symptoms.

A study at the National Institutes of Health (NIH) found that patients with schizophrenia were unable to benefit from explicit instructions and practice on the Wisconsin Card Sorting Test (WCST), a widely used test of executive functioning. The study was linked to data demonstrating that patients had diminished prefrontal blood flow in dorsolateral prefrontal cortex while responding to the WCST, implying that
schizophrenia was marked by an unmodifiable abnormality of the dorsolateral prefrontal cortex. The NIH work stimulated a series of mostly successful laboratory demonstrations that WCST performance deficits, albeit widespread, are neither endemic to the illness nor immutable. For example, one study demonstrated that WCST performance could be enhanced by financial reinforcement and specific instructions. Other laboratories have since produced comparable and enduring effects using similar training strategies and extended practice alone.

ETHICAL ISSUES

The ethics of conducting rehabilitation strategies are generally the same as for conducting other psychotherapies. Two issues come up regularly, however: avoiding infantilization and maintaining confidentiality. The first concerns the risk of viewing the patient as unable to make adult choices, such as whether to participate in rehabilitation, where to live, whether or not to work, and whether or not to use drugs and alcohol. Although it may be more of a value than an ethical standard, psychiatric rehabilitation is based on the assumption that the practitioner and the patient are in a partnership to facilitate recovery and improve quality of life. The basic model involves collaboration and shared decision making and does not portray the practitioner as an authority or parental figure. When patients make what appear to be bad choices, the practitioner must consider the patient’s right to choose and whether the choice is dangerous versus simply not the choice the practitioner would make. If the choice, in fact, is potentially harmful, a collaborative process of considering alternatives is more likely to produce good choices than an authoritative, admonitory approach.

Failure to consider the patient as a partner also leads to violations of confidentiality. Practitioners sometimes assume that they are the primary arbiters of what information to share with parents, other clinicians, and other agencies. In fact, in most circumstances that do not involve the safety of patients or others, the patient should be the arbiter of what information is shared with whom. For example, in supported employment, the patients always determine whether to disclose information about their illnesses to employers.

28.13 Combined Psychotherapy and Pharmacotherapy

The use of psychotropic drugs in combination with psychotherapy has become widespread. In fact, it has become the standard of care for many patients seen by psychiatrists. In this therapeutic approach, psychotherapy is augmented by the use of pharmacological agents. It should not be a system in which the therapist meets with the patient on an occasional or irregular basis to monitor the effects of medication or to make notations on a rating scale to assess progress or side effects; rather, it should be a system in which both therapies are integrated and synergistic. In many cases, it has been demonstrated that the results of combined therapy are superior to either type of therapy used alone. The term *pharmacotherapy-oriented psychotherapy* is used by some practitioners to refer to the combined approach. The methods of psychotherapy used can vary immensely, and all can be combined with pharmacotherapy when indicated.

**INDICATIONS FOR COMBINED THERAPY**

A major indication for using medication when conducting psychotherapy, particularly for those patients with major mental disorders such as schizophrenia or bipolar disorder, is that psychotropics reduce anxiety and hostility. This improves the patient’s capacity to communicate and to participate in the psychotherapeutic process. Another indication for combined therapy is to relieve distress when the signs and the symptoms of the patient’s disorder are so prominent that they require more rapid amelioration than psychotherapy alone may be able to offer. In addition, each technique may facilitate the other; psychotherapy may enable the patient to accept a much needed pharmacological agent, and the psychoactive drug may enable the patient to overcome resistance to entering or continuing psychotherapy (Table 28.13-1).

</tbody>
</table>

The reduction of symptoms, especially anxiety, does not decrease the patient’s motivation for psychoanalysis or other insight-oriented psychotherapy. In practice, drug-induced symptom reduction improves communication and motivation. All therapies
have a cognitive base, and anxiety generally interferes with the patient’s ability to gain cognitive understanding of the illness. Drugs that decrease anxiety facilitate cognitive understanding. They can improve attention, concentration, memory, and learning in patients who suffer from anxiety disorders.

**NUMBER OF TREATING CLINICIANS**

Any number of clinicians can be involved in treatment of a psychiatric disorder. In *one-person therapy*, the psychiatrist provides individual psychotherapy and medication treatment. Multiperson therapy is a form of treatment in which one therapist (who may be a psychiatrist, psychologist, or a social worker) conducts psychotherapy while the other therapist (always a psychiatrist) prescribes medications. Other therapists may oversee marriage or family therapy or group therapy. The terms *cotherapy* or *triangular therapy* are sometimes used to describe permutations of multiperson therapy.

**COMMUNICATION AMONG THERAPISTS**

Whenever more than one clinician is involved in treatment, there should be regular exchanges of information. Some patients split the transference between the two; one therapist may be seen as giving and nurturing, and the other may be seen as withholding and aloof. Similarly, countertransference issues, such as one therapist’s identifying with the patient’s idealized or devalued image of the other therapist, can interfere with therapy. Those issues must be worked out, and the cotherapists must be compatible and respectful of each other’s orientation, so that the therapy program can succeed.

A therapist may have some concerns about the quality of the psychopharmacology or that the existing regimen needs to be reconsidered. For example, a patient may not be doing well on medication, experiencing significant side effects, or showing lack of sufficient improvement. Some patients may also be taking many different medications. When and if it is deemed in the patient’s interest to question the medication regimen or the prescriber’s skill, these misgivings should not be shared with the patient without first conferring with the prescribing physician.

If the therapist or pharmacologist, after a good-faith effort to understand the methods and course of treatment, still has misgivings about treatment, he or she should inform his or her counterpart that a second opinion would be useful. This should then be suggested to the patient without necessarily raising undue alarm. Communication between treating clinicians should take place as frequently as needed. No standard exists for how frequent that should be.

**ORIENTATIONS OF TREATING CLINICIANS**

The orientation of the treating psychiatrist or other clinician can influence the therapeutic process during combination treatment. Clinicians invariably bring a theoretical bias to the treatment setting. Some, for example, are oriented, by preference
and training, to practice a specific form of psychotherapy, such as psychoanalysis, cognitive-behavioral therapy (CBT), or group therapy. To these clinicians, psychotherapy is seen as the primary treatment modality, with pharmacological agents being used as an adjunct. Conversely, to a psychopharmacologically oriented psychiatrist, psychotherapy is seen as augmenting the use of medication. Although disagreement may arise on which approach represents the most active ingredient in clinical response, the optimal use of both modalities should complement each other.

In addition to having extensive training in one or more psychoanalytic or psychotherapeutic techniques, the psychiatrist who practices pharmacotherapy-oriented psychotherapy must have a comprehensive knowledge of psychopharmacology. That knowledge must include a thorough understanding of the indications for the use of each drug, the contraindications, the pharmacokinetics and pharmacodynamics, the drug–drug interactions (with all pharmacological agents, not only the psychoactive agents), and the adverse effects of medications. The psychiatrist must be able both to identify adverse effects and to treat them.

Nonpsychiatric physicians often use psychoactive agents inaccurately (too small or too large a dose for too short or too long a course), because they lack the requisite psychopharmacological knowledge, training, and experience. Psychotherapists who work with primary care physicians instead of psychiatrists should understand the limitations in depth of knowledge that these practitioners have and should seek a consultation with a psychiatrist if a patient is not responding to, or tolerating, medication. In some situations, it is preferable for psychotherapy and pharmacotherapy to be carried out by the same clinician; however, this is often not possible for a variety of reasons, including therapist availability, time limitations, and economic restraints, among others (Table 28.13-2).

Table 28.13-2
Clinical Situations in Which It Is Advantageous for One Psychiatrist to Provide Medication and Psychotherapy

| Patients with schizophrenia and other psychotic disorders who are not compliant with prescribed medication |
| Patients with bipolar I disorder who deny illness and do not cooperate with the treatment plan |
| Patients with serious or unstable medical conditions |
| Patients with severe borderline personality disorders |
| Impulsive and severely suicidal patients who are likely to require hospitalization |
| Patients with eating disorders who present complicated management problems |
| Patients who present a clinical picture in which the need for medication is unclear, thus requiring ongoing assessment |

**Therapist Attitudes**

Psychiatrists trained primarily as psychotherapists may prescribe medication more reluctantly than those who are more oriented toward biological psychiatry. Conversely, those who view medication as the preferred intervention for most psychiatric disorders...
may be reluctant to refer patients for psychotherapy. Therapists who are pessimistic about the value of psychotherapy or who misjudge the patient’s motivation may prescribe medications because of their own beliefs; others may withhold medication if they overvalue psychotherapy or undervalue pharmacological treatments. When a patient is in psychotherapy with someone other than the clinician prescribing medication, it is important to recognize treatment bias and to avoid contentious turf battles that put the patient in the middle of such conflict.

**Linkage Phenomenon**

At some point, patients may view the improvement being made in therapy as the result of a conscious or unconscious linkage between the psychopharmacological agent and the therapist. In fact, after being weaned from medication, patients often carry a pill with them for reassurance. In that sense, the pill acts as a transitional object between the patient and the therapist. Some patients with anxiety disorders, for example, may carry a single benzodiazepine tablet, which they take when they think they are about to have an anxiety attack. Then, the patient may report that the attack was aborted—before the medication could even have been absorbed into the bloodstream. In other cases, the pill is never taken, because the patient knows that the pill is available and gains reassurance from that fact. The linkage phenomenon is usually not seen unless the patient is in a positive transference to the therapist. Indeed, the therapist may use this phenomenon to his or her advantage by suggesting that the patient carry medication to use as needed. Eventually, the behavior has to be analyzed, and it is often found that the patient has attributed magical properties to the therapist that are then transferred to the medication. Some clinicians believe the effect to be the result of conditioning. After repeated trials, the sight of the medicine can decrease anxiety. The positive transference may also cause *transference cure* or *flight into health*, in which the patient feels better in an unconscious attempt to meet the presumed expectations of the prescribing physician. Therapists should consider this phenomenon if the patient reports rapid improvement well before a particular medication may reach its therapeutic level.

Rachel, a 25-year-old white woman, presented with depressive symptoms and abdominal pain. After an extensive psychiatric and medical evaluation, she was diagnosed with major depression of moderate severity and irritable bowel disorder. She began a course of CBT targeting her negative attributional style and low self-esteem, and she was taught relaxation and distraction techniques for her pain. After a 12-week trial, she experienced only partial remission of her symptoms and was offered an antidepressant, citalopram (Celexa) at 20 mg per day. Her depressive symptoms remitted within 1 month, and she was able to function better at work but socially remained hesitant to engage with her peers. Her abdominal pain persisted, and she began to exhibit a pattern of disordered eating, severely restricting her intake to 500 calories per day due to the “pain.” She experienced a 15-pound weight loss.
over the next several months. An intensive behavioral plan to target eating was begun, as well as continued probing of her negative cognitions relating to eating, pain, and newly emerging concerns that she would regain the weight too quickly and would become “fat.” She did not meet weight loss criteria for anorexia nervosa, although her cognitive distortions about her body image were extreme. These new concerns resulted in a relapse of her depressive symptoms, including suicidal ideation, and her citalopram was increased to 40 mg per day. She reported severe akathisia on this dose and refused to take any more medication, including an antidepressant of another class. Rachel did agree to intensify her therapy to twice weekly, and this allowed her to explore some of her conflicts, feelings, and thoughts that fostered her treatment-refractory illness. A combination of psychotherapy and hypnosis was used for this work. Over the next 6 months, Rachel revealed that she had been sexually abused as a child and this made her feel that she did not “deserve” to live or to eat and that the pain served to “punish” her for being bad. She also admitted that she resisted the medication “psychologically” because she felt that she did not deserve to get well. Her newly found insight, as well as the coping skills she developed in therapy, resulted in a reduction of her depressive symptoms, marked improvement in her eating habits with normalization of her weight, and decreased abdominal pain. She maintained these gains over the next year, including normalization of her daily functioning, a promotion at work, and the ability to tolerate the intimacy of a boyfriend. (Courtesy of E. M. Szigethy, M.D., Ph.D., and E. S. Friedman, M.D.)

**COMPLIANCE AND PATIENT EDUCATION**

**Compliance**

Compliance is the degree to which a patient carries out the recommendations of the treating physician. Compliance is fostered when the doctor–patient relationship is a positive one, and the patient’s refusal to take medication may provide insight into a negative transference situation. In some cases, the patient acts out hostilities by noncompliance, rather than by becoming aware of, and ventilating, such negative feelings toward the doctor. Medication noncompliance may provide the psychiatrist with the first clue that a negative transference is present in an otherwise compliant patient who had appeared to be agreeable and cooperative.

**Education**

Patients should know the target signs and symptoms that the drug is supposed to reduce, the length of time they will be taking the drug, the expected and unexpected adverse effects, and the treatment plan to be followed if the current drug is unsuccessful. Although some psychiatric disorders interfere with patients’ abilities to comprehend that information, the psychiatrist should relay as much of the information as possible. The clear presentation of such material is often less frightening than are patients’ fantasies.
about drug treatment. The psychiatrist should tell patients when they may expect to begin to receive benefits from the drug. That information is most critical when the patient has a mood disorder and may not observe any therapeutic effects for 3 to 4 weeks.

Some patients’ ambivalent attitudes toward drugs often reflect the confusion about drug treatment that exists in the field of psychiatry. Patients often believe that taking a psychotherapeutic drug means they are not in control of their lives or they may become addicted to the drug and have to take it forever. Psychiatrists should explain the difference between drugs of abuse that affect the normal brain and psychiatric drugs that are used to treat emotional disorders. They should also point out to patients that antipsychotics, antidepressants, and antimanic drugs are not addictive in the way in which, for example, heroin is addictive. The psychiatrist’s clear and honest explanation of how long the patient should take the drug helps the patient adjust to the idea of chronic maintenance medication if that is the treatment plan. In some cases, the psychiatrist may appropriately give the patient increasing responsibility for adjusting the medications as the treatment progresses. Doing so often helps the patient feel less controlled by the drug and supports a collaborative role with the therapist.

ATRIBUTION THEORY

Attribution theory is concerned with how persons perceive the causes of behavior. According to attribution theory, persons are likely to attribute changes in their own behavior to external events, but are likely to attribute another’s behavior to internal dispositions, such as that person’s personality traits. Research on drug effects by attribution theorists has shown that, when patients take medication and their behaviors change, they attribute it to the drug and not to any changes that occur within themselves. Accordingly, it may be unwise to describe a drug as extremely strong or effective, because if it does have the desired effect, the patient may believe that is the only reason he or she got better; if the drug does not work, the patient may assume his or her condition is incurable. Therapists do best by presenting the use of drugs and psychotherapy as complementary or adjunctive, as neither standing alone and both being needed for improvements or cure to occur.

MENTAL DISORDERS

Depressive Disorders

Some patients and clinicians fear that medication covers over the depression and that psychotherapy is impeded. Instead, medication should be viewed as a facilitator in overcoming the anergia that can inhibit the communication process between doctor and patient. The psychiatrist should explain to the patient that depression interferes with interpersonal activity in a variety of ways. For instance, depression produces withdrawal and irritability, which alienate significant others who may otherwise gratify the strong dependency needs that make up much of depressive psychodynamics.
If medication is stopped, the psychiatrist should be alert for signs and symptoms of a recurrent major depressive episode. Medication may have to be reinstituted. Before doing so, however, carefully review any stress, especially rejections, that could have precipitated recurrent major depressive disorder. A new episode of depression may occur because the patient is in a stage of negative transference, and the psychiatrist must try to elicit negative feelings. In many cases, the ventilation of angry feelings toward the therapist without an angry response can serve as a corrective emotional experience, and a major depressive episode necessitating medication can thereby be forestalled. Depressed patients are generally maintained on their medication for 6 months or longer after clinical improvement. The cessation of pharmacotherapy before that time is likely to result in a relapse.

Combined treatment has been shown to be superior to either therapy used alone in the treatment of major depression. It is associated with improved social and occupational functioning and improved quality of life compared with either therapy alone.

**Bipolar I Disorder**

Patients taking lithium (Eskalith) or other treatments for bipolar I disorder are usually medicated for an indefinite period of time to prevent episodes of mania or depression. Most psychotherapists insist that patients with bipolar I disorder be medicated before starting any insight-oriented therapy. Without such premedication, most patients with bipolar I disorder are unable to make the necessary therapeutic alliance. When those patients are depressed, their abulia seriously disrupts their flow of thoughts, and the sessions are nonproductive. When they are manic, their flow of associations can be rapid, and their speech can be so pressured that the therapist could be flooded with material and may be unable to make appropriate interpretations or to assimilate the material into the patient’s disrupted cognitive framework.

The practice guideline of the American Psychiatric Association (APA) for bipolar disorder recommends combined therapy as the best approach. It increases compliance, decreases relapse, and reduces the need for hospitalization.

**Substance Abuse**

Patients who abuse alcohol or drugs present the most difficult challenge in combined therapy. They are often impulsive, and, although they may promise not to abuse a substance, they may do so repeatedly. In addition, they frequently withhold information from the psychiatrist about episodes of abuse. For that reason, some psychiatrists do not prescribe any medication to such patients, especially not those substances with a high abuse potential, such as benzodiazepines, barbiturates, and amphetamines. Drugs with no abuse potential, such as amitriptyline (Elavil) and fluoxetine (Prozac), have an important role in treating the anxiety or depression that almost always accompanies substance-related disorders. The psychiatrist conducting psychotherapy with such patients should have no reservations about sending the patient to a laboratory for
random urine toxicological tests.

Anxiety Disorders

Anxiety disorders encompass obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), generalized anxiety disorder, phobic disorders, and panic disorder with or without agoraphobia. Many drugs are effective in managing distressing signs and symptoms. As the symptoms are controlled by medication, patients are reassured and develop confidence that they will not be incapacitated by the disorder. That effect is particularly strong in panic disorder, which is often associated with anticipatory anxiety about the attack. Depression can also complicate the symptom picture in patients with anxiety disorders and has to be addressed pharmacologically and psychotherapeutically. Studies have shown that patients with anxiety disorders who receive ongoing psychotherapy are less likely to experience relapse compared with patients who receive medication alone.

Schizophrenia and Other Psychotic Disorders

Included in the group of schizophrenia and other disorders are schizophrenia, delusional disorder, schizoaffective disorder, schizophreniform disorder, and brief psychotic disorder. Drug treatment for those disorders is always indicated, and hospitalization is often necessary for diagnostic purposes, to stabilize medication, to prevent danger to self or others, and to establish a psychosocial treatment program that may include individual psychotherapy. In attempting individual psychotherapy, the therapist must establish a treatment relationship and a therapeutic alliance with the patient. The patient with schizophrenia defends against closeness and trust and often becomes suspicious, anxious, hostile, or regressed in therapy. Before the advent of psychotropics, many psychiatrists were fearful for their own safety when working with such patients. Indeed, many assaults occurred.

Individual psychotherapy for schizophrenia is labor intensive, expensive, and not often attempted. The recognition that combined psychotherapy and pharmacotherapy have a greater chance of success than either type of therapy alone may reverse that situation. The psychiatrist who conducts such combined therapy must be especially empathic and must be able to tolerate the bizarre manifestations of the illness. The patient with schizophrenia is exquisitely sensitive to rejection, and individual psychotherapy should never be started unless the therapist is willing to make a total commitment to the process.

OTHER ISSUES

Evidence suggests that therapy can induce physical changes in the nervous system. Eric Kandel has provided elegant proof, winning the Nobel Prize for demonstrating that environmental stimuli produce lasting changes in the synaptic architecture of living organisms. Imaging studies have begun to show that patients who show clinical
improvement from psychotherapy show changes in brain metabolism that are similar to that seen in patients successfully treated with medications.

Still, some patients do well on only one form of treatment. Even with identical diagnoses, not all patients respond to the same treatment regimens. Success may be as dependent on the knowledge and quality of the clinician as on the potential benefit of a particular drug.

A real dilemma when combining treatment is the additional direct costs of two treatments. Although successful treatment results in reduced costs to society, the cost of treatment is usually narrowly defined by the patient as out-of-pocket expenses and by insurance and managed care companies as payments to the physician or hospital. Restrictions placed on the frequency and cost of visits to mental health professionals by managed care organizations, however, encourage the use of medication rather than psychotherapy.

28.14 Genetic Counseling

Medical geneticists and specially trained and qualified genetic counselors have traditionally provided genetic counseling to patients in need of such help. Many psychiatrists, however, are also well placed to provide genetic education and counseling because they often have knowledge of their clients’ needs and family histories and have ongoing therapeutic relationships. The ideal approach for providing psychiatric genetic counseling is through a multidisciplinary team approach, with collaboration between genetics and mental health professionals. Genetic professionals often seek collaboration with a psychiatrist for those with difficult psychiatric medical or family histories. Genetic professionals also seek collaboration or referral for persons with a psychiatric disorder; those who are having difficulty adapting to a genetic-related diagnosis; those dealing with the death of a family member; or those who are experiencing persistent difficulty with decision making regarding prenatal diagnosis or genetic testing. In turn, genetic professionals can be available for professional consultation regarding risk assessment, the collection and construction of complicated family medical histories, and the availability and limitations of genetic or genomic testing.

DEFINITIONS

Genetic counseling is the process of helping people to understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease. According to the National Society of Genetic Counseling, it integrates three factors: (1) interpretation of family and medical histories to assess the chance of disease occurrence or recurrence; (2) education about inheritance, testing, management, prevention, resources, and research; and (3) counseling to promote informed choices and adaptation to the risk or condition. The process aims to minimize distress and facilitate adaptation, to increase one’s feeling of personal control, and to facilitate informed decision making and life planning.

Genetic counseling is not limited to considerations of the genetic contributions of disease. Genetic counseling also considers environmental components of the presenting disease along with genetic ones. Table 28.14-1 lists common terminology used in the field of genetic counseling. Figure 28.14-1 illustrates a complex family medical history.
presented in the form of a pedigree.

**FIGURE 28.14-1**

**Table 28.14-1**
Genetic Terminology
Disorders can recur in families for many reasons, including the functioning of genes (single genes vs. polygenic) (Table 28.14-2), shared environmental exposures, a combination of genetic and environmental factors (multifactorial), and cultural transmission. **Single gene disorders** are caused by defects in one particular gene, and they often have simple and predictable inheritance patterns. By contrast, most psychiatric disorders are **multifactorial** in etiology, influenced by multiple genes as well as environmental factors, making them more difficult to predict.

**Table 28.14-2**
Examples of Psychiatric Disorders Recognized as Having a Genetic Component to Their Etiology

| Psychotic disorders: Schizophrenia, schizoaffective disorder |
|-----------------|------------------------------------------------------------------|
| Mood disorders: Bipolar disorder, recurrent unipolar depression |
| Personality disorders: Antisocial personality disorder, schizotypal disorder |
| Anxiety disorders: Generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, phobia |
| Substance-related disorders: Substance dependence and abuse |
| Eating disorders: Anorexia nervosa, bulimia |
| Childhood disorders: Attention-deficit/hyperactivity disorder, autism, chronic tic disorders, including Tourette’s disorder |
| Memory disorders: Alzheimer’s disease |
Two phenomena that further complicate genetic counseling include penetrance and expressivity. **Penetrance** refers to the portion of individuals with a specific genotype who also manifest that genotype at the phenotype level. If all individuals who carry the dominant gene show any phenotype of the gene, the gene is said to be **completely penetrant**. Currently, only rare examples exist of known genes for mental disorders that demonstrate complete penetrance of symptoms in the presence of a single gene. One such example is early-onset familial Alzheimer’s disease resulting from mutations in the amyloid precursor protein (APP) located on the long arm of chromosome 21. In contrast, **expressivity** refers to the extent to which a genotype is expressed. In the case of variable expressivity, the trait can vary in expression from mild to severe, but is never completely unexpressed in individuals who have the gene. The genes that result in most mental disorders are believed to regulate a wide spectrum of traits demonstrating variability of expression (spectrum disorders).

**COMPONENTS OF THE GENETIC COUNSELING PROCESS**

Requests for genetic counseling are often initiated by the client’s or relatives’ questions about the disorder that is present in the family. In the case of mental illness, the questions are often posed to the treating psychiatrist. The client’s questions are most effectively addressed through an interactive process that provides the client, as well as the professional, with information pertinent to the next step in the communication process. The basic components of genetic counseling are outlined in Table 28.14-3.

### Table 28.14-3

<table>
<thead>
<tr>
<th>Steps and Process of Genetic Counseling</th>
</tr>
</thead>
<tbody>
<tr>
<td>Solicit and clarify the client’s presenting questions and goals for genetic counseling.</td>
</tr>
<tr>
<td>Collect and review medical and family medical history.</td>
</tr>
<tr>
<td>Identify support systems.</td>
</tr>
<tr>
<td>Verify diagnoses in proband and other affected family members when possible.</td>
</tr>
<tr>
<td>Address issues and concerns identified through the genetic counseling process.</td>
</tr>
<tr>
<td>Assess the client’s emotional and intellectual capacity before proceeding to determine the approach to the provision of education and counseling.</td>
</tr>
<tr>
<td>Provide information at cognitively appropriate levels.</td>
</tr>
<tr>
<td>Note that the processing of emotional reactions is intertwined with the provision of information.</td>
</tr>
<tr>
<td>Assess the personal meaning of the information and the client’s willingness to negotiate various risks and burdens.</td>
</tr>
<tr>
<td>When applicable, assist the client in arriving at a decision by discussing available options; discuss benefits and limitations of each alternative.</td>
</tr>
<tr>
<td>Assist the client with adapting to the risk status in the family.</td>
</tr>
<tr>
<td>Assist in formulating a plan that the client is able to carry out.</td>
</tr>
<tr>
<td>Provide follow-up counseling and support. Continue to assess the client’s and family’s understanding of the information and the effect of the information, risks, or decisions.</td>
</tr>
</tbody>
</table>

**Contracting**

Contracting is a vital portion of the psychiatric genetic counseling session. Often the goals of the session will vary based on the consultand’s histories and reason(s) for concern. The provider should work with the consultand at the beginning of the session to define mutual goals.
Documentation of Diagnosis, Collection, and Review of Family Medical History

A family medical history (FMH) is collected, and at least a three-generation pedigree is constructed. The collection of FMH begins with the individual seeking information. The consultand (or client) is the individual seeking information. Proband is the term used to identify the affected person within the family who first brought the family to medical attention. The FMH should be comprehensive and include the following information: ages (or dates of birth) of each family member, the age at which the diagnosis was made for individuals with the disorder, pregnancy losses (including the gestational length along with the recognized cause, if known), the recognized cause and age of any deceased family members, and ethnic backgrounds (Table 28.14-4).

### Table 28.14-4
Topics Included in the Family Medical History

<tr>
<td>H. Birth defects, mental retardation or learning disabilities, and unusual medical conditions</td>
</tr>
<tr>
<td>I. The age and sex of at-risk family members (which may play a role in risk assessment)</td>
</tr>
</tbody>
</table>

Confirmation or clarification of the diagnosis is essential to the provision of valid information within the session. This usually requires obtaining medical records to clarify or to confirm the suspected diagnosis in the relatives. Depending on the situation, genetic testing may be available for at-risk members in families with single-gene disorders; but because DNA (deoxyribonucleic acid) testing for most mental disorders is not yet an option, risk assessment is based solely on analysis of the pedigree.

The collection and review of the FMH with the patient might elicit or recall intense feelings of sadness, guilt, anxiety, or anger. Furthermore, the graphic presentation of the family history may bring to light a more concrete realization of an individual’s risks; therefore, attention to the patient’s affect is important throughout the process. Specific issues that may hinder an accurate psychiatric family history and may increase consultand affect related to family history are listed in Table 28.14-5.

### Table 28.14-5
Issues that Can Hinder an Accurate Psychiatric Family History

1. Age of symptom onset and at diagnosis
2. Subjective assessment of illness severity and treatment response
3. Potentially important environmental exposures (e.g., birth trauma, cannabis use, head injury)
4. Symptomatic, undiagnosed individuals
5. Suggest a psychiatric evaluation
6. Undiagnosed individuals treated with psychiatric medications
7. Developmental history (e.g., has the individual achieved normal milestones for age, such as independent living and employment for adults?)
8. Social history
9. Substance abuse
10. Suicide
11. Birth defects, mental retardation or learning disabilities, and unusual medical conditions
12. The age and sex of at-risk family members (which may play a role in risk assessment)
Communication of Risk and Decision Making

Individuals vary in their level of understanding risks. The provision of risk information is best approached in a balanced and accurate manner that is tailored to the patient as much as possible. There is the temptation to use nonnumeric phrases of probability (e.g., often, rarely, most likely); however, the meaning of these nonnumeric phrases is highly subjective and their use in the genetic counseling session introduces the potential for bias.

Ideally, risks should be presented in several different ways, taking clues from interactions with the client that inform the approach. Some examples of approaches to assist the client’s understanding of risks include stating numeric risks as percentages (25 percent) and as fractional risks (one-in-four chance). It is important to frame risks from the perspective of a negative and a positive outcome; for example, there is a 1 percent chance that the test will result in a complication and a 99 percent chance that there will be no complication.

Owing to the high rate of co-occurring disorders and the wide phenotypic range of psychiatric disorders, patients should be informed of potential risks for disorders other than those that brought them to genetic counseling. An example of this is the risk to first-degree relatives of an individual diagnosed with bipolar disorder. In this situation, the risk for bipolar disorder is increased for first-degree relatives, as are the risks for unipolar disorder, schizoaffective disorder, and cyclothymia.

It should be made clear that the risks are determined from populations and not derived from individuals and, therefore, are estimates at best. Table 28.14-6 provides a compilation of recurrence risks from various referenced sources in the literature.

</tbody>
</table>
PSYCHOSOCIAL COUNSELING AND SUPPORT

Setting the stage for the inclusion of psychological and emotional issues can occur early in the process by verbalizing the intent to provide factual information, as well as fostering a discussion of the client's reaction to the information. Insight into the client’s perspective and experiences with the disorder, values, beliefs, and family dynamics can begin to be obtained through asking what brings the client to the genetic counseling session. Eliciting this personal information provides a relational context from which the provider can assess concerns and emotional issues. Collection of the FMH can also provide a backdrop of the client’s and family’s experiences with the disorder. The
A couple in their mid-30s with a 10-year history of infertility had been trying to adopt a child for a number of years. Recently, the adoption agency they were working with told them of a baby who was being placed for adoption because the biological mother was affected with bipolar disorder and did not feel that she could provide adequate care for the baby. The FMH collected on the newborn baby did not identify others in his family with mental disorders. The recurrence risk for bipolar disorder to the newborn was, therefore, estimated to be between 5 and 20 percent, with additional risks for other mental disorders. The couple individually reacted quite disparately to the estimated risks. In attempting to help them clarify the factors contributing to their feelings regarding the risks, the husband shared his experience with a childhood neighbor who had “some kind of mental illness” and detailed the “torment and agony” that the child brought to the family. Retorting, the woman shared the fact that her coworker also had bipolar disorder and did “just fine” at work with the help of medication. She therefore did not feel that the risks for mental disorders were of concern. The psychiatrist facilitated the couple’s discussion of the spectrum and meaning of mental illness, along with recurrence risks in the context of a genetic education and counseling session. Although the couple did not come to agreement at that meeting over the potential for adopting the child, they did feel that the information and sharing of experiences and perspectives about mental disorders were beneficial. They agreed to return in 1 week after further considering the issues in an effort to reach a decision regarding the adoption. (Courtesy of Holly L. Peay, M.S., and Donald W. Hadley, M.S.)

CHALLENGES POSED BY PRESYMPTOMATIC AND SUSCEPTIBILITY GENETIC TESTING

Psychiatrists will be on the front line for receiving requests for genetic counseling and testing because of their established relationship between patients and families with mental disorders. The identification of these risks will most likely occur before the discovery or availability of preventative options. The option of knowing risks without preventative options raises concerns regarding the impact of such knowledge on the individual’s mood, anxiety, distress, self-image, reproductive decisions, career decisions, family relationships, insurability, employment, and, potentially, other areas.

A model for the provision of presymptomatic genetic testing is provided through the protocol developed for Huntington’s disease (see the Hereditary Disease Foundation web site at [www.hdfoundation.org](http://www.hdfoundation.org)). This model recommends conducting education, counseling, and evaluative sessions over an extended period of time (3 to 4 months), during which time information is provided, questions are addressed, and counseling is initiated, thus maximizing informed decision
making. The process is most appropriately undertaken in the absence of other stressful events (e.g., death of a family member, diagnosis of the disease in another family member, job loss, and divorce).

Studies suggest that most individuals receiving information of their increased risk for the disease in their family experience significantly more anxiety, depression, and psychological distress and have poorer perception of their health over the short term (within 1 month after receiving test results) compared with their baseline levels, but no difference over the long term (as long as 1 year after the receipt of results) compared with pretest levels. Consideration should also be given to the impact of such information on the spouse, because initial studies have suggested that the spouse may experience higher levels of depression related to the presymptomatic diagnosis than the client. Furthermore, partners of gene-positive individuals may experience increased levels of intrusive thoughts, avoidance, and hopelessness over the short and long term compared with baseline levels.

ETHICAL, LEGAL, AND SOCIAL CONSIDERATIONS

Certain individuals and families may experience significant levels of stigma associated with the identification of a genetic disorder, a situation already familiar to individuals and families with mental illness. The added knowledge of a hereditary component may heighten stigmatization. Conversely, having an identified, biological basis may supplant current public perceptions that mental illness is somehow a personal or family failure in moral, spiritual, or attitudinal perspectives.

Questions frequently arise about the privacy of an individual’s genetic information, the ability of employers or insurers to access such information, and the potential of using the information against them by denying insurance, raising rates to unreasonable levels, or denying jobs, and a host of other possible concerns. Currently, no overarching federal laws comprehensively protect citizens of the United States from the potential of these abuses, although significant efforts are continuing in this regard. The status of existing and proposed state and federal laws can be reviewed through the web site of the National Human Genome Research Institute (www.genome.gov).

**28.15 Mentalization-Based Therapy and Mindfulness**

*Mentalization* is a relatively new term that has been defined as the process of thinking and feeling about oneself and others. Mindfulness is somewhat similar except that it applies only to oneself. In both modalities the person attempts to stay aware of thoughts, feelings, affects, moods, and somatic sensations; but in mentalization that exercise extends to another person as well. It is an interpersonal transaction. The origins of mentalization-based therapy (MBT) have been attributed to two psychologists, Jon Allen and Peter Fonagy, and one psychiatrist, Anthony Batemen, who described the process in their book *Mentalizing in Clinical Practice*, much of which formed the basis for this section.

From a theoretical perspective, MBT is eclectic in that it combines theories from a number of analytic and nonanalytic schools of thought: Sigmund Freud and psychoanalysis; John Bowlby and attachment theory; Aaron Beck and cognitive therapy; Carl Rogers and client-centered therapy; and Gerald Klerman and interpersonal therapy. The amalgam of these techniques developed into the unique method of treatment known as mentalization.

Mindfulness has its origins in Buddhist philosophy and the term was used in the 19th century to refer to a meditative technique in which the person stayed in the moment focusing on innermost feelings and states of mind. Mindfulness and mentalization rely on the same process; the person focuses on being in the “here and now.” Some have described the differences between MBT and mindfulness by stating that in MBT one is “mindful of mindfulness.”
The novel focus of a mindfulness approach is on present-moment, nonjudgmental awareness of consciousness, that is, noticing one’s thoughts and feelings in the moment and accepting them without judging or trying to change them. In many ways, mindfulness is a variation of self-monitoring in which patients attend to and increase awareness of thoughts, feelings, and behaviors. However, increased awareness of these phenomena from a mindfulness perspective does not involve analyzing them to determine how best to modify them. Instead, patients might be asked to imagine their thoughts and feelings as if they were written on cards carried by marchers in a parade or as if they were pieces of luggage on a conveyor belt. They are asked to observe internal phenomena without reaction.

**THERAPEUTIC APPROACHES**

Freud believed that all action was preceded by thought (conscious or unconscious), and in mentalization the therapist helps the patient “capture” the thought so that actions are understood more fully. Bowlby saw attachment of the infant to the mother or to the primary caregiver as the basis for a sense of security later in life. In mentalization, the therapist relies on a secure attachment with the patient to enable him or her to explore the inner world of emotions and the outer world of action, both of which elicit anxiety. Beck proposed that cognitive distortions of the self (e.g., “She doesn’t like me”) could be reversed by positive cognitions (e.g., “I don’t know if she likes me; many people do”). The mentalization therapist corrects distortions through interpretation and helps the patient test the validity of negative thoughts. The patient is encouraged to use the mechanism of empathy to step into the shoes of the other and to experience what that person may be thinking or feeling. It is the antithesis of self-centeredness. Klerman emphasized transferential distortions—a Freudian concept—that interfere with interpersonal relationships. The mentalization therapist attempts to strengthen the patient’s capacity to see the other as he or she really is by not “mind reading” or fantasizing about what the other person thinks. Rogers emphasized the autonomy of the patient vis-à-vis the therapist who was not to be seen as all knowing and omnipotent. The mentalization therapist relies on a certain degree of self-disclosure to reinforce that concept. In that sense, the therapist serves as a role model for coping with the anxieties of daily living and the vicissitudes of life. The task of the therapist is neither to judge nor advise. He or she takes a “mentalizing stance,” which is neutral and allows the patient to resolve conflict using innate resources that were previously unrecognized. MBT also allows the patient to mentalize the future by anticipating events and his or her reactions to them. In MBT emotion is experienced in a controlled and modulated manner, which can be a valuable therapeutic experience for persons whose affect is restricted because of fear. Fonagy has described what he calls the mentalizing stance as “an attitude of openness, inquisitiveness and curiosity about what’s going on in the others’ mind and in your own.” In that sense, the use and development of empathy is a core component of the process.

Mindfulness is the practice of paying attention in a particular way—on purpose, in
the present moment, and without judgment. Mindfulness skills include the ability to observe, describe, and participate fully in one’s actions in a nonjudgmental, mindful, and effective manner. Some of the work in mindfulness-based approaches centers on decreasing what is known as *experiential avoidance* or the unwillingness to experience negative feelings, thoughts, and sensations. Persons who are skilled and well practiced in mindfulness are more adept at taking their automatic thoughts “with a grain of salt.” Upset by a series of interpersonal disappointments, a person may think “I am never going to let myself care about people ever again.” However, as he or she takes stock of this thought, the individual quickly concludes that this self-statement is neither realistic nor constructive. Instead, the person recognizes that the emotional pain of the moment is tied up in biased thinking, and that the solution to recovering from negative life events requires learning from the difficult situations and moving on.

Mindfulness approaches are aimed at improving patients’ abilities to regulate their emotions and tolerating distress may then be considered, in effect, exposure exercises. Although techniques that increase patients’ nonjudgmental awareness of internal sensations may be considered at odds with attempts to change thoughts in a way that is typical within cognitive therapy, the techniques may be considered comparable to exposure-based procedures that help patients to reduce anxiety and distress associated with certain types of thoughts and images through repeated exposure to those thoughts and images. The overlap between cognitive-behavioral treatments and mindfulness-based approaches continues to be hotly debated.

**INDICATIONS**

Mentalization has been applied to a number of clinical disorders, one of which is autism. In autism, both child and adult are impaired socially because they are less sensitive to emotional cues given by others. They have difficulty empathizing, which makes their social interactions awkward and stilted. Mentalization focuses on teaching empathy and improving social engagement with others.

Patients with antisocial personality disorder may also benefit from MBT. Such patients are manipulative, give no thought to the results of their actions, lack the capacity for loyalty, and are unable or unwilling to empathize with others. MBT focuses on the core issues of their psychopathology. If a secure attachment can be made between patient and therapist the basic trust that is lacking in the antisocial person may be developed for the first time. MBT has also been of use in patients with borderline personality disorder.

Mindfulness-based treatments have been demonstrated to be effective for a wide range of psychological problems, including borderline personality disorder, anxiety, chronic pain, depression, and stress. The approaches also have been used to reduce dysfunction in patients with medical conditions (e.g., cancer, multiple sclerosis) and to increase general well-being. Patients also learn to develop a greater tolerance for feelings of anxiety or depression and recognize that those states are often transitory, which may enable them to deal with conflict with greater confidence.

29.1 General Principles of Psychopharmacology

Psychopharmacologic advances continue to dramatically expand the parameters of psychiatric treatments. Greater understanding of how the brain functions has led to more effective, less toxic, better-tolerated, and more specifically targeted therapeutic agents. With the ever-increasing sophistication and array of treatment options, clinicians, however, must remain aware of potential adverse effects, drug–drug (and drug–food or drug–supplement) interactions, and how to manage the emergence of unwanted or unintended consequences. Newer drugs could ultimately lead to side effects that are not recognized initially. Keeping up with the latest research findings is increasingly important as these findings proliferate. A thorough understanding of the management of medication-induced side effects (either through treating the effect with another agent or substituting another primary agent) is necessary.

CLASSIFICATION

Medications used to treat psychiatric disorders are referred to as psychotropic drugs. These drugs are commonly described by their major clinical application, for example, antidepressants, antipsychotics, mood stabilizers, anxiolytics, hypnotics, cognitive enhancers, and stimulants. A problem with this approach is that, in many instances, drugs have multiple indications. For example, drugs such as the selective serotonin reuptake inhibitors (SSRIs) are both antidepressants and anxiolytics, and the serotonin-dopamine antagonists (SDAs) are both antipsychotics and mood stabilizers.

Psychotropic drugs have also been organized according to structure (e.g., tricyclic), mechanism (e.g., monoamine oxidase inhibitor [MAOI]), history (e.g., first generation, traditional), uniqueness (e.g., atypical), or indication (e.g., antidepressant). A further problem is that many drugs used to treat medical and neurological conditions are routinely used to treat psychiatric disorders.

In addition, psychotropic drug terminology can be confusing. The first pharmaceutical agents used to treat schizophrenia were termed tranquilizers. When newer drugs emerged as therapies for anxiety, a distinction was drawn between major and minor tranquilizers. At first, antidepressants were tricyclic antidepressants (TCAs) or MAOIs. In the 1970s and 1980s, as newer antidepressant drugs emerged, they were labeled as second- or third-generation antidepressants. More recently, older agents used as treatments for psychosis became known as typical, conventional, or traditional neuroleptics. Newer ones became atypical neuroleptics. In order to eliminate much of this confusion, in this section,
drugs are presented according to shared mechanism of action or by similarity of structure to provide consistency, ease of reference, and comprehensiveness.

PHARMACOLOGICAL ACTIONS

Both genetic and environmental factors influence individual response to, and tolerability of, psychotropic agents. Thus, a drug that may not prove effective in many patients with a disorder can dramatically improve symptoms in others. In these cases, identification of characteristics that might predict potential candidates for that drug becomes important, but often remains elusive.

Drugs, even within the same class, are distinguished from one another by often subtle differences in molecular structure, types of interactions with neurotransmitter systems, differences in pharmacokinetics, the presence or absence of active metabolites, and protein binding. These differences, combined with the biochemistry of the patient, account for the profile of efficacy, tolerability, and safety and the risk-to-benefit ratio for the individual. These multiple variables, some poorly understood, make it difficult to predict a drug’s effect with certainty. Nevertheless, knowledge of the nature of each property increases the likelihood of successful treatment. The clinical effects of drugs are best understood in terms of pharmacokinetics, which describes what the body does to a drug, and pharmacodynamics, which describes what the drug does to the body.

Pharmacokinetics and pharmacodynamics need to be seen in the context of the underlying variability among patients with respect to how drug effects are expressed clinically. Patients differ in their therapeutic response to a drug and the experience of side effects. It is increasingly clear that these differences have a strong genetic basis. Pharmacogenetics research is attempting to identify the role of genetics in drug response.

DRUG SELECTION

Although all U.S. Food and Drug Administration (FDA)-approved psychotropics are similar in overall effectiveness for their indicated disorder, they differ considerably in their pharmacology and in their efficacy and adverse effects on individual patients. The ability of a drug to prove effective, thus, is only partially predictable and is dependent on poorly understood patient variables. Nevertheless, it is possible that some drugs have a niche in which they can be uniquely helpful for a subgroup of patients, without demonstrating any overall superiority in efficacy. No drug is universally effective, and no evidence indicates the unambiguous superiority of any single agent as a treatment for any major psychiatric disorders. The only exception, clozapine (Clozaril), has been approved by the FDA as a treatment for cases of treatment-refractory schizophrenia.

Decisions about drug selection and use are made on a case-by-case basis, relying on the individual judgment by the physician. Other factors in drug selection are the characteristics of the drug and the nature of the patients illness. Each of these components affects the probability of a successful outcome.
**Pharmacodynamics**

The time course and intensity of a drug’s effects are referred to as its *pharmacodynamics*. Major pharmacodynamic considerations include receptor mechanisms, the dose–response curve, the therapeutic index, and the development of tolerance, dependence, and withdrawal phenomena. Drug mechanism of action is subsumed under pharmacodynamics. The clinical response to a drug, including adverse reactions, results from an interaction between that drug and a patient’s susceptibility to those actions. Pharmacogenetic studies are beginning to identify genetic polymorphisms linked to individual differences in treatment response and sensitivity to side effects.

**Mechanisms**

The mechanisms through which most psychotropic drugs produce their therapeutic effects remain poorly understood. Standard explanations focus on ways that drugs alter synaptic concentrations of dopamine, serotonin, norepinephrine, histamine, γ-aminobutyric acid (GABA), or acetylcholine. These changes are said to result from receptor antagonists or agonists, interference with neurotransmitter reuptake, enhancement of neurotransmitter release, or inhibition of enzymes. Specific drugs are associated with permutations or combinations of these actions. For example, a drug can be an agonist for a receptor, thus stimulating the specific biological activity of the receptor, or an antagonist, thus inhibiting the biological activity. Some drugs are partial agonists, because they are not capable of fully activating a specific receptor. Some psychotropic drugs also produce clinical effects through mechanisms other than receptor interactions. For example, lithium (Eskalith) can act by directly inhibiting the enzyme inositol-1-phosphatase. Some effects are closely linked to a specific synaptic effect. For example, most medications that treat psychosis share the ability to block the dopamine type 2 (D₂) receptor. Similarly, benzodiazepine agonists bind a receptor complex that contains benzodiazepine and GABA receptors.

Further illustrating the fact that the mechanisms of action of psychotropic drugs remain only partially understood are observations that medications that do not directly target monoamine neurotransmitters can be remarkably effective in treating some psychiatric disorders. For example, ketamine (Ketalar), an anesthetic agent that targets glutamate, can rapidly and dramatically alleviate symptoms of depression when given as a slow infusion. Another example involves the antibiotic minocycline (Solodyn), which has been shown to have antidepressant effects. Along with other findings, this suggests that the immune system and inflammatory responses may underlie some mood disorders.

Accounts of so-called mechanisms of action should nevertheless be kept in perspective. Explanations of how psychotropic drugs actually work that focus on synaptic elements represent an oversimplification of a complex series of events. If merely raising or lowering levels of neurotransmitter activity is associated with the clinical effects of a
drug, then all drugs that cause these changes should produce equivalent benefits. This is not the case. Multiple obscure actions, several steps removed from events at neuronal receptor sites, are probably responsible for the therapeutic effects of psychotropic drugs. These downstream elements are postulated to represent the actual reasons that these drugs produce clinical improvement. A glossary of terms related to receptor drug interactions is given in Table 29.1-1.

### Table 29.1-1
**Glossary of Receptor Drug Interactions**

<table>
<thead>
<tr>
<th>Receptor Interaction</th>
<th>Definition</th>
<th>Examples and Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Agonist (full agonist)</td>
<td>A drug or medication that binds to a specific receptor producing an effect identical to that usually produced by the neurotransmitter affecting that receptor. Drugs are often designed as receptor agonists to treat a variety of diseases and disorders in which the original neurotransmitter is missing or diminished.</td>
<td>Full agonists include opioids such as morphine, methadone, oxycodone, hydrocodone, heroin, codeine, meperidine, propoxyphene, and fentanyl. Benzodiazepines act as agonists at the GABA receptor complex.</td>
</tr>
<tr>
<td>Antagonist</td>
<td>A compound that binds to a receptor that blocks or reduces the action of another substance (agonist) at the receptor site involved. Antagonists that compete with an agonist for a receptor are competitive antagonists. Those that antagonize by other means are noncompetitive antagonists.</td>
<td>Flumazenil is a competitive benzodiazepine receptor antagonist. It competitively inhibits the activity at the benzodiazepine recognition site on the GABA/ benzodiazepine receptor complex. It is the purest antagonist synthesized. Drugs used in the treatment of schizophrenia block dopamine 2 receptors. Examples of opioid antagonists include naltrexone and naloxone.</td>
</tr>
<tr>
<td>Partial agonist (mixed agonist)</td>
<td>A compound that (even when fully occupying a receptor) possesses affinity for a receptor, but elicits a partial pharmacological response at the receptor involved. Partial agonists are often structural analogs of agonist molecules. If neurotransmitter concentrations are low, partial agonists may behave as an agonist. This is why these medications are sometimes called mixed agonists.</td>
<td>Buprenorphine is a partial agonist that produces typical opioid agonist effects and side effects, such as euphoria and respiratory depression, but its maximal effects are less than those of full agonists like heroin and methadone. When used at low doses buprenorphine produces sufficient agonist effect to enable opioid-addicted individuals to discontinue the drugs with fewer withdrawal symptoms.</td>
</tr>
<tr>
<td>Inverse agonist</td>
<td>An inverse agonist is an agent that binds to the same receptor as an agonist for that receptor but produces the opposite pharmacological effect.</td>
<td>Several inverse agonists are currently in clinical development. One particular example is RO15-4513, which is the inverse agonist of the benzodiazepine class of drugs. RO15-4513 and the benzodiazepines both utilize the same GABA binding site on neurons, yet RO15-4513 has the opposite effect, producing severe anxiety rather than the sedative and anxiolytic effects associated with benzodiazepines. Cannabinoid inverse agonists have been found to reduce appetite, the opposite of the craving effect associated with cannabis.</td>

GABA, γ-aminobutyric acid.
(Table by Norman Susman, M.D.)

### SIDE EFFECTS

Side effects are an unavoidable risk of medication treatment. Although it is impossible to have an encyclopedic knowledge of all possible adverse drug effects, prescribing clinicians should be familiar with the more common adverse effects, as well as those with serious medical consequences. No single text or document, including the product information, contains a complete list of possible treatment-emergent events.

Side effect considerations include the probability of its occurrence, its impact on a patient’s quality of life, its time course, and its cause. Just as no one drug is certain to
produce clinical improvement in all patients, no side effect, no matter how common, occurs in every patient. When concurrent medical disorders or a history of a similar adverse reaction puts a patient at increased risk for a side effect, it is logical to consider prescribing a compound not typically associated with that adverse reaction.

Side effects can result from the same pharmacological action that is responsible for a drug’s therapeutic activity or from an unrelated property. In examples of the latter, some of the most common adverse effects of the TCAs are caused by blockade of muscarinic acetylcholine receptors or histamine 2 receptors. If a patient is sensitive to these effects, alternative agents without these properties should be prescribed. When side effects are manifestations of the drug’s presumed mechanism of action, side effects may be unavoidable. Thus, blockade of serotonin reuptake by SSRIs can cause nausea and sexual dysfunction. The D2 blockade of drugs used to treat psychosis can cause extrapyramidal side effects. Agonist action of benzodiazepine receptors can cause ataxia and daytime sleepiness. In these cases, additional medications are frequently used to make the primary agent better tolerated.

**Time Course**

Adverse effects differ in terms of their onset and duration. Some side effects appear at the outset of treatment and then rapidly diminish. Nausea occurring with SSRIs or venlafaxine (Effexor) and sedation occurring with mirtazapine (Remeron) are good examples of early, time-limited side effects. Early-onset, but persistent, side effects include dry mouth that is associated with noradrenergic reuptake inhibition or antimuscarinic activity. Some side effects appear later in treatment (*late-appearing side effects*) and, sometimes, may be just the opposite of adverse events early in treatment. For example, patients may typically lose weight during early treatment with SSRIs, only to find, over time, a reversal occurs, so that they gain weight. Similarly, early activation or agitation may be followed by constant fatigue or apathy. Because most data about new drugs come from short-term studies, generally 8 weeks in duration, early-onset side effects are overrepresented in product information and descriptions of newly marketed information. It is essential that clinicians follow the letters to the editor sections of journals and other sources of information to update their understanding of the true side effect profile of a drug.

Adverse effects differ in their impact on compliance and potential to cause harm. Depending on a patient’s threshold of tolerance for a side effect and the impact on quality of life, side effects can lead to drug discontinuation. Examples of serious side effects include agranulocytosis (clozapine), Stevens-Johnson syndrome (lamotrigine [Lamictal]), hepatic failure (nefazodone [Serzone]), stroke (phenelzine [Nardil]), and heart block (thioridazine [Mellaril]). Overall, the risk of life-threatening side effects with psychotropics is low. Drugs that carry such a risk should be monitored more closely, and the prescribing physician should take into account whether the potential clinical benefits justify the additional risk. Any drug with a serious risk, as reflected in a black box warning, is generally used less extensively than would otherwise be the case.
In the case of haloperidol (Haldol) and other dopamine receptor antagonists, long-term complications, such as tardive dyskinesia, have been well documented. Emerging evidence also suggests that the use of dopamine antagonists is associated with a small increase in the risk of breast cancer and that this is related to larger cumulative doses. In cases in which serious risk is associated with a drug, closer medical monitoring of medication treatment is warranted. Because the most widely used psychotropics, such as the SSRIs and serotonin-dopamine antagonists, have only been in use since the 1980s or 1990s, there is less certainty about long-term effects, but no evidence indicates that side effects are not merely extensions of those already evident during initial therapy. It should also be kept in mind that most drugs used in the treatment of chronic medical disorders have not been in use sufficiently long to provide assurances about unintended long-term adverse effects.

Suicidal Ideation and Antidepressant Treatment

The issue of antidepressant-associated suicide has become front-page news, the result of an analysis suggesting a link between medication use and suicidal ideation among children, adolescents, and adults up to age 24 in short-term (4 to 16 weeks), placebo-controlled trials of nine newer antidepressant drugs. The data from trials involving more than 4,400 patients suggested that the average risk of suicidal thinking or behavior (suicidality) during the first few months of treatment in those receiving antidepressants was 4 percent, twice the placebo risk of 2 percent. No suicides occurred in these trials. The analysis also showed no increase in suicide risk among the 25 to 65 age group. Antidepressants reduced suicidality among those over age 65.

Following public hearings on the subject, in October 2004, the FDA requested the addition of black box warnings—the most serious warning placed on the labeling of a prescription medication—to all antidepressant drugs, old and new. This action raised alarm among parents and physicians and prompted an explosion of advertisements by malpractice attorneys. Most important, antidepressant prescriptions written for adolescents declined, whereas those for adults flattened, after years of growth.

A large study of real world patients published in the January 2006 issue of the American Journal of Psychiatry raised serious doubt about true antidepressants and suicidality and about the wisdom of the FDA’s decision to change the labeling. The study examined suicides and hospitalizations for suicide attempts in the medical records of 65,103 members of a nonprofit insurer in the Pacific Northwest that covers about 500,000 people who received antidepressants from 1992 to 2003. It found that (1) newer antidepressants were associated with a more rapid and greater reduction in risk than older types of antidepressants and (2) patients were significantly more likely to attempt or commit suicide in the month before they began drug therapy than in the 6 months after starting it.

This is not the first time credible evidence has contradicted a significant link between antidepressant use and increased risk of suicide. At the hearings that led to the black box warning, John Mann of Columbia University presented population data showing that
since 1987, the year before fluoxetine (Prozac) became the first marketed SSRI, suicide
rates in the United States began dropping, and that areas in the United States with the
highest SSRI prescription rates had the biggest decline in suicides. For every 10 percent
increase in prescription rates, the US suicide rate declined 3 percent.

Another study, a review of 588 case files of patients aged 10 to 19, found that a 1
percent increase in antidepressant use was associated with a decrease of 0.23 suicides
per 100,000 adolescents per year.

A more important question, given how slight the risk may be, if indeed it exists, is
whether as a result of the FDA’s ill-considered actions, some depressed patients are not
getting potentially life-saving treatment. Epidemiological findings from several
countries, including the United States, have shown that decreased prescribing of
antidepressants for depressed children and adolescents resulted in an increase in suicide
rates in those populations.

**Side Effects Associated with Newer Medications**

All medications are associated with side effects. The clinician should be aware of these,
be able to recognize them, and take appropriate measures to treat them.

**Somnolence.** Sedation is often an intended effect of many psychotropic drugs,
especially when used to treat insomnia, anxiety, or agitation. Daytime sleepiness, or
somnolence, is also an unwanted adverse event, however. It is important for the
clinician to alert patients to the possibility of sedation and to document that the person
was advised to exercise caution when operating any type of vehicle or mechanical
equipment. Some somnolence results from a carryover of nighttime use of drugs as
hypnotics. Even with drugs, such as the SSRIs, which are activating to many patients,
somnolence can be problematic. In some instances, it results from impairment of sleep
quality. Chronic use of SSRIs can cause some patients to experience a subjective sense of
fatigue, exhaustion, or yawning, even with adequate amounts of sleep. Management of
unwanted somnolence includes adjustment of dose or timing of administration,
switching to alternative medications, addition of small doses of stimulants, or the
addition of modafinil (Provigil).

**Gastrointestinal Disturbances.** The major gastrointestinal (GI) side effects of
the older antidepressant and antipsychotic drugs consisted primarily of constipation and
dry mouth, a consequence of their antimuscarinic activity. Most of the newer drugs have
little antimuscarinic activity, but do have effects on the serotonin system. Most of the
body’s serotonin is in the GI tract, and serotonergic drugs often cause varying degrees of
stomach pain, nausea, flatulence, and diarrhea. In most cases, these side effects are
transient, but some persons never accommodate and must switch to another class of
drugs. Initial use of lower doses or use of delayed release preparations are the most
effective strategies for minimizing GI side effects.
**Movement Disorders.** The introduction of serotonin-dopamine antagonists has greatly reduced the incidence of medication-induced movement disorders, but varying degrees of dose-related parkinsonism, akathisia, and dystonia still occur. Risperidone (Risperdal) most closely resembles the older agents in terms of these side effects. Olanzapine (Zyprexa) also causes more extrapyramidal effects than clinical trials suggested. Aripiprazole (Abilify) causes severe akathisia. There have been rare reports of SSRI-induced movement disorders, ranging from akathisia to tardive dyskinesia.

**Sexual Dysfunction.** The use of psychiatric drugs can be associated with sexual dysfunction—decreased libido, impaired ejaculation and erection, and inhibition of female orgasm. In clinical trials with the SSRIs, the extent of sexual side effects was grossly underestimated, because data were based on spontaneous reports by patients. The rate of sexual dysfunction in the original fluoxetine product information, for example, was less than 5 percent. In subsequent studies in which information about sexual side effects was elicited by specific questions, the rate of SSRI-associated sexual dysfunction was found to be between 35 and 75 percent. In clinical practice, patients are not likely to report sexual dysfunction spontaneously to the physician, so it is important to ask about this side effect. Also, some sexual dysfunctions may be related to the primary psychiatric disorder. Nevertheless, if sexual dysfunction emerges after pharmacotherapy has begun and the primary response to treatment has been positive, it may be worthwhile to attempt to treat the symptoms. Long lists of possible antidotes to these side effects have evolved, but few interventions are consistently effective, and few have more than anecdotal evidence to support their use. The clinician and patient should consider the possibility of sexual side effects with a patient when selecting a drug and switching treatment to another drug that is less or not at all associated with sexual dysfunction if this adverse effect is not acceptable to the patient.

**Weight Gain.** Weight gain accompanies the use of many psychotropic drugs as a result of retained fluid, increased caloric intake, decreased exercise, or altered metabolism. Weight gain can also occur as a symptom of disorder, as in bulimia or atypical depression, or as a sign of recovery from an episode of illness. Treatment-emergent increase in body weight is a common reason for noncompliance with a drug regimen. No specific mechanisms have been identified as causing weight gain, and it appears that the histamine and serotonin systems mediate changes in weight associated with many drugs used to treat depression and psychosis. Metformin (Glucophage) has been reported to facilitate weight loss among patients whose weight gain is attributed to use of serotonin-dopamine reuptake inhibitors and valproic acid (Depakene). Valproate (Depacon), as well as olanzapine, has been linked to the development of insulin resistance, which could induce appetite increase, with subsequent weight increase. Weight gain is a noteworthy side effect of clozapine (Clozaril) and olanzapine. Genetic factors that regulate body weight, as well as the related problem of diabetes mellitus, seem to involve the 5-HT$_{2C}$ receptor. There is a genetic polymorphism of the promoter
region of this receptor, with significantly less weight gain in patients with the variant allele than in those without this allele. Drugs with a strong $5\text{-HT}_{2C}$ affinity would be expected to have a greater impact on body weight of patients with a polymorphism of the $5\text{-HT}_{2C}$ receptor promoter region.

**Weight Loss.** Initial weight loss is associated with SSRI treatment but is usually transient, with most weight being regained within the first few months. Bupropion (Wellbutrin) has been shown to cause modest weight loss that is sustained. When combined with diet and lifestyle changes, bupropion can facilitate more significant weight loss. Topiramate (Topamax) and zonisamide (Zonegran), marketed as treatments for epilepsy, sometimes produce substantial, sustained loss of weight.

**Glucose Changes.** Increased risk of glucose abnormalities, including diabetes mellitus, is associated with weight increase during psychotropic drug therapy. Clozapine and olanzapine are associated with a greater risk than other serotonin-dopamine antagonists of abnormalities in fasting glucose levels, as well as hyperosmolar diabetes and ketoacidosis. This dysregulation of glucose homeostasis appears to be drug induced and increases glucagon.

**Hyponatremia.** Hyponatremia is associated with oxcarbazepine (Trileptal) and SSRI treatment, especially in elderly patients. Confusion, agitation, and lethargy are common symptoms.

**Cognitive Impairment.** Cognitive impairment means a disturbance in the capacity to think. Some agents, such as the benzodiazepine agonists, are recognized as causes of cognitive impairment. Other widely used psychotropics, such as the SSRIs, lamotrigine (Lamictal), gabapentin (Neurontin), lithium, TCAs, and bupropion, however, are also associated with varying degrees of memory impairment and word-finding difficulties. In contrast to the benzodiazepine-induced anterograde amnesia, these agents cause a more subtle type of absent-mindedness. Drugs with anticholinergic properties are likely to worsen memory performance.

**Sweating.** Severe perspiration unrelated to ambient temperature is associated with TCAs, SSRIs, and venlafaxine. This side effect is often socially disabling. Attempts can be made to treat this side effect with alpha agents, such as terazosin (Hytrin) and oxybutynin (Ditropan).

**Cardiovascular Disturbances.** Newer agents are less likely to have direct cardiac effects. Many older agents, such as TCAs and phenothiazines, affected blood pressure and cardiac conduction. Thioridazine (Mellaril), which has been in use for decades, has been shown to prolong the QTc interval in a dose-related manner and may increase the risk of sudden death by delaying ventricular repolarization and causing
torsades de pointes. Newer drugs are now routinely scrutinized for evidence of cardiac effects. A promising treatment for psychosis, sertindole (Serlect), was not marketed because the FDA would have required a black box warning. Slight QTc effects noted with ziprasidone (Geodon) delayed the marketing of that drug. Clozapine can cause myocarditis in rare cases of which the clinician should be aware.

Rash. Any medication is a potential source of a drug rash. Some psychotropics, such as carbamazepine (Equetro, Tegretol) and lamotrigine, have been linked to an increased risk of serious exfoliative dermatitis. Commonly referred to as Stevens-Johnson syndrome, this condition is a systemic, immune-mediated reaction that can prove fatal or result in permanent scarring or blindness. All patients should be informed about the potential seriousness of lesions that are widespread, that occur above the neck, that involve the mucous membranes, and that may be associated with fever and lymphadenopathy. If such symptoms manifest, a patient should be instructed at the time that the medication is prescribed to go immediately to an emergency department.

Idiosyncratic and Paradoxical Drug Responses

Idiosyncratic reactions occur in a very small percentage of patients taking a drug. The reactions are not related to the known pharmacologic properties, and most likely represent a genetically based abnormal sensitivity to a drug. A paradoxical response represents the manifestation of a clinical effect the opposite of what is expected. In March 2007, the FDA reported dissociative-like states associated with certain sedative hypnotics. These included behaviors such as sleepwalking, binge eating, aggressive outbursts, and night driving of which the patient was unaware. Table 29.1-2 lists the drugs required to have warning labels for that effect.

Therapeutic Index
**Therapeutic index** is a relative measure of the toxicity or safety of a drug and is defined as the ratio of the median toxic dose to the median effective dose. The median toxic dose is the dose at which 50 percent of patients experience a specific toxic effect, and the median effective dose is the dose at which 50 percent of patients have a specified therapeutic effect. When the therapeutic index is high, as it is for haloperidol, it is reflected by the wide range of dosages in which that drug is prescribed. Conversely, the therapeutic index for lithium is quite low, thus requiring careful monitoring of serum lithium levels in patients for whom the drug is prescribed.

**Overdose**

Safety in overdose is always a consideration in drug selection. Almost all of the newer agents, however, have a wide margin of safety when taken in overdose. By contrast, a 1-month supply of TCAs could be fatal. The depressed patients they were used to treat are the group most at risk to attempt suicide. Because even the safest drugs can sometimes produce severe medical complications, especially when combined with other agents, clinicians must recognize that the prescribed medication can be used in an attempt to commit suicide. Although it is prudent to write nonrefillable prescriptions for small quantities, this practice passes along increased copay costs to the patient. In fact, many pharmacy benefit management programs encourage the prescribing of a 3-month supply of medication.

In cases in which suicide is a major concern, an attempt should be made to verify that the medication is not being hoarded for a later overdose attempt. Random pill counts or asking a family member to dispense daily doses may be helpful. Some patients attempt suicide just as they are beginning to recover. Large quantities of medications with a low therapeutic index should be prescribed judiciously. Another reason to limit the number of pills prescribed is the possibility of accidental ingestion of medications by children in the household. Psychotherapeutic medications should be kept in a safe place.

Physicians who work in emergency rooms should know which drugs can be hemodialyzed. The issues involved are complex and are not based on any single chemical property of the drug. For example, it is generally presumed that drugs with low protein binding are good candidates for dialysis. Venlafaxine, however, is only 27 percent protein bound and is too large as a molecule dialyzed. Hemodialysis is effective for treating overdose of valproic acid.

**Pharmacokinetics**

*Pharmacokinetic drug interactions* are the effects of drugs on the plasma concentrations of each other, and *pharmacodynamic drug interactions* are the effects of drugs on the biological activities of each other. Pharmacokinetic concepts are used to describe and predict the time course of drug concentrations in different parts of the body, such as plasma, adipose tissue, and the central nervous system (CNS). From a clinical perspective, pharmacokinetic methods help explain or predict the onset and duration of drug activity and interactions between drugs that alter their metabolism or excretion.
Pharmacogenetic research focuses on finding variant alleles that alter drug pharmacokinetics and pharmacodynamics. Researchers are attempting to identify genetic differences in how enzymes metabolize psychotropics, as well as CNS proteins directly involved in drug action. Likely, identification of patient genotypes will facilitate prediction of clinical response to different types of drugs.

Most clinicians need to consult charts or computer programs to determine when potential interactions may occur and, if so, how clinically relevant they may be. Whenever possible, it is preferable to use a medication that produces minimal risk of drug interactions. Also, it is recommended that prescribers know the interaction profiles of the drugs they most commonly prescribe.

Examples of pharmacokinetic interactions include one drug increasing or decreasing the concentrations of a coadministered compound. These types of interactions can also lead to altered concentrations of metabolites. In some cases, there may also be interference with the conversion of a drug to its active metabolite. Enormous variability exists among patients with respect to pharmacokinetic parameters, such as drug absorption and metabolism. Another type of interaction is represented by interactions involving the kidney. Commonly used medications, such as angiotensin-converting enzyme (ACE) inhibitors, nonsteroidal anti-inflammatory drugs (NSAIDs), and thiazides, decrease renal clearance of lithium, increasing the likelihood of severe elevations of lithium. Drug interactions can occur pharmacokinetically or pharmacodynamically.

Pharmacogenetics is being used to study why patients differ in the way they metabolize drugs. In patients who are ultrarapid or extensive metabolizers, the concentrations of a drug may be lower than expected.

PATIENT-RELATED FACTORS

Response to medication and sensitivity to side effects are influenced by factors related to the patient. This is why there is no one-size-fits-all approach to pharmacological treatment. Patient-related variables include diagnosis, genetic factors, lifestyle, overall medical status, concurrent disorders, and history of drug response. A patient’s attitude toward medication in general, aversion to certain types of side effects, and preference for a specific agent also need to be considered.

Diagnosis

Failure to correctly diagnose a disorder diminishes the likelihood of optimal drug selection. Misdiagnosis not only can result in a missed opportunity, but it also can, at times, produce worsening of symptoms. Inadvertently diagnosing a patient in the depressed phase of bipolar disorder as having unipolar depression can induce mania or rapid cycling. Treatment failure or exacerbation of symptoms should prompt a reassessment of the working diagnosis.

Past Treatment Response
A specific drug should be selected according to the patient’s history of drug response (compliance, therapeutic response, adverse effects), the patient’s family history of drug response, the profile of adverse effects for that drug with regard to the particular patient, and the prescribing clinician’s usual practice. If a drug has previously been effective in treating a patient or a family member, the same drug should be used again. For reasons that are not understood, however, some patients fail to respond to a previously effective agent when challenged again. A history of severe adverse effects from a specific drug is a strong indicator that the patient would not be compliant with that particular drug.

It is helpful if patients can recall the details of past psychotropic drug treatment: the drugs prescribed, in what dosages, for how long, and in what combinations. Because of their mental disorders, many patients, however, are poor historians. If possible, patients’ medical records should be obtained to confirm their reports. Family members are a good source of collateral information.

Response in Family Members
It is widely held that drug responses cluster in families. Thus, response to a drug in a relative is an indicator of whether a patient might also benefit from that medication. Although no conclusive evidence supports this as a consideration in drug selection, existing studies do confirm that a history of positive response to treatment with a drug should be considered in making treatment decisions.

Concurrent Medical or Psychiatric Disorders
Initial assessment should elicit information about coexisting medical disorders. In some cases, a medical disorder may be responsible for the symptoms. Patients with thyroid disease who are not adequately treated may appear depressed. Sleep apnea produces depression and cognitive impairment. Rare conditions, such as Kleine-Levin syndrome, can mimic bipolar disorder. A drug should be selected that minimally exacerbates any preexisting medical problems that a particular patient may have.

Recreational drug use, excessive consumption of alcohol, and frequent ingestion of caffeine-containing beverages can complicate and even undermine psychotropic drug treatment. These compounds possess significant psychoactive properties and, in some cases, may represent the source of the patient’s symptoms. It is reasonable to ask patients to abstain from use of these substances, at least until the benefits of psychototropic drug treatment have been unequivocally established. Gradual reintroduction of moderate amounts of alcohol, tea, and coffee can then take place. Patients can then observe for themselves whether there are any untoward effects on their clinical status.

INFORMED CONSENT AND PATIENT EDUCATION
Establishing trust and providing motivation to comply with the medication regimen are
essential components of successful treatment. Patients should be informed about treatment options and the probable side effects and unique benefits of each treatment. Patient preference should be respected, unless a compelling advantage exists involving efficacy, tolerability, or safety with an alternative agent. If a particular medication is being recommended, the reasons for this recommendation should be explained. Patients are more likely to continue taking their medication if they fully understand the reasons why it is being prescribed.

A strong therapeutic alliance between a clinician and a patient is always helpful. Given the unpredictability of medication response, the frequent occurrence of side effects, and underlying ambivalence about, or fear of taking, medication, a positive, trusting relationship serves to improve patient compliance. Repeated failed trials may be needed before a response is seen. A patient’s confidence in the physician’s knowledge and judgment enables medication trials and more complex regimens, such as the use of multiple medications.

Discussions about drug selection should be documented in notes, but a signed informed consent is not needed. Surprisingly, patients who are informed of potential adverse effects report a higher incidence of side effects but do not have higher rates of premature discontinuation.

How the patient and family are engaged in the treatment plan can determine the success of treatment. The psychodynamic meaning of pharmacotherapy to the patient and family and environmental influences, psychosocial stressors, and support should be explored. Some patients may view drug treatment as a panacea, and others may view it as the enemy. With the patient’s consent, relatives and other clinicians should be instructed about the reasons for the drug treatment, as well as the expected benefits and potential risks.

**DOSING, DURATION, AND MONITORING**

**Dosing**

The clinically effective dose for treatment depends on the characteristics of the drug and patient factors, such as inherited sensitivity and ability to metabolize a drug, concurrent medical disorders, use of concurrent medications, and history of exposure to previous medications.

Plasma concentrations of many psychotropics can vary up to tenfold. Thus, to some extent, the optimal dose for an individual is ultimately determined by trial and error, guided by the empirical evidence of the usual dose range for that drug. In some cases, it may prove helpful to test patients for genetic polymorphisms involving hepatic enzymes. Patients who are ultrarapid metabolizers of certain drugs may require higher than normal dosing. Slow metabolizers might demonstrate side effects and even toxicity at very low doses.

Some drugs demonstrate a clear relationship between increases in dose and clinical response. This dose–response curve plots the drug concentration against the effects of the drug.
The **potency** of a drug refers to the relative dose required to achieve certain effects, not to its efficacy. Haloperidol, for example, is more potent than chlorpromazine (Thorazine), because approximately 5 mg of haloperidol is required to achieve the same therapeutic effect as 100 mg of chlorpromazine. These drugs, however, are equal in their clinical efficacy—that is, the maximal clinical response achievable by administration of a drug.

Drugs must be used in effective dosages for sufficient periods. Although drug tolerability and safety are always considerations, subtherapeutic doses and incomplete therapeutic trials should be avoided. The use of inadequate doses merely exposes the patient to the risk of side effects, without providing the probability of therapeutic benefit. In view of the wide margin of safety associated with most currently prescribed medications, more risk exists in underdosing than in overshooting the recommended dose range.

Time of dosing is usually based on the plasma half-life of a drug and its side effect profile. Sedating drugs are given all at night or with disproportionate daily doses at night. The opposite is true with activating drugs. The frequency of dosing is less clear-cut. Most dosing regimens of psychotropic drugs, such as once-a-day versus divided doses, are based on measurements of plasma concentrations rather than receptor occupancy in the brain. Evidence suggests a significant dissociation exists between brain and plasma kinetics. Reliance on plasma kinetics as the basis for dosing regimens leads to misunderstanding of necessary schedules.

As a rule, psychotropic drugs should be used continuously. Exceptions are the use of drugs for insomnia, acute agitation, and severe situational anxiety. A common mistake is the use of high-potency benzodiazepines, such as alprazolam (Xanax) and clonazepam (Klonopin), only after an attack has begun. These drugs should be used as part of a regular schedule to prevent attacks.

Some patients who experience sexual dysfunction while being treated with SSRIs take a drug holiday, that is, they skip a daily dose from time to time to facilitate sexual performance.

Intermittent dosing regimens of SSRIs have been found to be effective as a treatment for premenstrual dysphoric disorder. The drugs are taken daily during the 2-week luteal phase of the menstrual cycle.

**Duration of Treatment**

A common question from a patient is “How long do I need to take the medication?” The answer depends on multiple variables, including the nature of the disorder, the duration of symptoms, the family history, and the extent to which the patient tolerates and benefits from the medication. Patients can be given a reasonable explanation of the probabilities but should be told that it is first best to see if the medication works for him or her and whether any side effects are acceptable. Any more definitive discussion of treatment duration can be held once the degree of success is clear. Even patients with a philosophical aversion to the use of psychotropic drugs may elect to stay on medication.
indefinitely if the magnitude of improvement is great. Most psychiatric disorders have high rates of chronicity and relapse. Because of this, long-term treatment is often needed to prevent recurrence. Nevertheless, the fact remains that psychotropic drugs are not said to cure the disorders they treat but rather to help control the symptoms.

Treatment is conceptually broken down into three phases: the initial therapeutic trial, the continuation, and the maintenance phase. The initial period of treatment should last at least several weeks because of the delay in therapeutic effects that characterizes most classes of psychotropic drugs. The required duration of a therapeutic trial of a drug should be discussed at the outset of treatment, so that the patient does not have unrealistic expectations of an immediate improvement in symptoms. Patients are more likely to experience side effects early in the course of pharmacotherapy than any relief from their disorder. In some cases, medication may even exacerbate some symptoms. Patients should be counseled that a poor initial reaction to medication is not an indicator of the ultimate outcome of treatment. For instance, many patients with panic disorder develop jitteriness or an increase in panic attacks after starting on tricyclic or SSRI treatment. Benzodiazepine agonists are an exception to the rule that clinical onset is delayed. In most cases, their hypnotic and antianxiety effects are evident immediately.

Ongoing use of medication, however, does not provide absolute protection against relapse. Continuation therapy provides clinically and statistically significant protective effects against relapse. The optimal duration of continuation or maintenance therapy is variable and dependent on the clinical history of the patient. Early-onset chronic major depression, for example, has a more severe course and greater comorbidity than late-onset chronic major depression. In addition to early onset, a history of multiple past episodes and severity and length of a current episode would make longer, even indefinite, treatment appropriate.

**Frequency of Visits**

Until an unequivocal response to treatment occurs, patients should be seen as frequently as circumstances warrant. The frequency of follow-up or monitoring visits is determined by clinical judgment. In severely ill patients, this might mean several times a week. Patients on maintenance therapy, even when stable, need monitoring, but no consensus exists on the frequency of follow-up therapy. Three months is a reasonable interval between visits, but 6 months may be adequate after long-standing treatment.

**LABORATORY TESTS AND THERAPEUTIC BLOOD MONITORING**

Laboratory testing and therapeutic blood monitoring should be based on clinical circumstances and the drugs being used. For most commonly used psychotropic drugs, routine testing is not required. No currently available laboratory test can confirm the diagnosis of a mental disorder.

Pretreatment tests are routine as part of a workup to establish baseline values and to rule out underlying medical problems that may be causing the psychiatric symptoms or that might complicate treatment with drugs. Results of recently performed tests should
be obtained. With agents known to cause cardiac conduction changes, a pretreatment electrocardiogram (ECG) should be obtained before initiating treatment. With lithium and clozapine, the possibility of serious changes in thyroid, renal, hepatic, or hematological functions requires pretreatment and ongoing monitoring with appropriate laboratory tests.

As a result of both anecdotal and research findings of sometimes severe glucose dysregulation during treatment primarily with SDAs, the FDA has suggested that patients being treated with any atypical antipsychotic be monitored for the emergence of diabetes.

Certain circumstances present in which it is necessary or useful to use plasma concentrations to monitor a patient’s condition. These include the monitoring of drugs with narrow therapeutic indexes, such as lithium; drugs with a therapeutic window, the optimal dose range for a therapeutic response; drug combinations that can lead to interactions that raise drug concentrations of medications or their metabolites, which can cause toxicity; unexplained toxicity at normal therapeutic doses; and failure to respond in a patient who may be noncompliant. A clinician should have no reservations about requesting random urine toxicological tests in a patient who abuse substances.

TREATMENT OUTCOMES

The goal of psychotropic treatment is to eliminate all manifestations of a disorder, thus enabling the patient to regain the ability to function as well and to enjoy life as fully as before he or she became ill. This degree of improvement to below the syndromal threshold is defined as remission.

Response and Remission

Remission is the preferred outcome of treatment, not only because of the immediate impact on functioning and state of mind, but also because emerging evidence suggests that patients in remission are less likely to experience relapse and recurrence of their disorder.

Patients who improve but do not experience a full resolution are considered to be responders. They may exhibit significant improvement but continue to experience symptoms. In depression studies, response is usually defined as a 50 percent or greater decrease from baseline on a standard rating scale, such as the Hamilton Depression (HAM-D) Scale or the Montgomery-Asberg Depression Rating Scale (MADRS). Remission is defined as an absolute score of 7 or less on the HAM-D or 10 or less on the MADRS. Expectations about the likely degree of improvement should be based on what is known about the responsiveness of specific disorders to medication therapy. Obsessive-compulsive disorder (OCD) and schizophrenia, for example, are more likely to be associated with residual manifestations of illness than major depression or panic disorder. The probability of full remission from OCD with SSRI treatment alone over a 2-year period is less than 12 percent, and the probability of partial remission is approximately 47 percent.
Treatment Failure
The initial treatment plan should anticipate the possibility that the medication may be ineffective. A next-step strategy should be in place at the initiation of treatment. Repeated drug failures should prompt reassessment of the patient. First, was the original diagnosis correct? In answering this question, the clinician should include the possibility of an undiagnosed medical condition or recreational drug use as the cause of the psychiatric symptoms.

Second, are the observed symptoms related to the original disorder, or are they actually adverse effects of the drug treatment? Some antipsychotic drugs, for example, can produce akinesia, which resembles psychotic withdrawal, or akathisia and neuroleptic malignant syndrome, which resemble increased psychotic agitation. Long-term use of SSRIs can produce emotional blunting, which can mimic depression.

Intolerance of side effects may be the most common reason for treatment failure. Third, was the drug administered at an appropriate dosage for a sufficient length of time? Because absorption and metabolism of drugs can vary greatly in patients, the clinician may need to measure plasma levels of a drug to ensure a sufficient dose of the drug.

Fourth, did a pharmacokinetic or pharmacodynamic interaction with another drug that the patient was taking reduce the efficacy of the newly prescribed drug? Fifth, did the patient take the drug as directed? Drug noncompliance is a common clinical problem that arises as a result of complicated drug regimens (more than one drug in more than one daily dosage), adverse effects (especially if unnoticed by the clinician), and poor patient education about the drug treatment plan. Patients may discontinue medication when they recover, thinking that they are cured and no longer benefiting from the medication.

Treatment Resistance
Some patients fail to respond to repeated trials of medication. No single factor can explain the ineffectiveness of the various interventions in these cases. Strategies in these cases include the use of drug combinations, high-dose therapy, and use of unconventional drugs. Limited evidence is available on the comparative success rates associated with any given strategy.

Tolerance
The development of tolerance is marked by a need, over time, to use increased doses of a drug for it to maintain a clinical effect. This decreased responsiveness to a drug occurs after repeated doses. Tolerance also describes decreased sensitivity to adverse effects of the drug, such as nausea. This phenomenon is used as the basis for starting some drugs at subtherapeutic doses, with the plan to adjust the schedule once the patient can tolerate higher doses. Clinical tolerance appears to represent changes in the CNS, such as altered receptor configuration or density. Drugs with similar pharmacological actions
often exhibit cross-tolerance.

**Sensitization**

Clinically manifested as the reverse of tolerance, sensitization is said to occur when sensitivity to a drug effect increases over time. In these cases, the same dose typically produces more pronounced effects as treatment progresses.

**Withdrawal**

The development of physiological adaptation to a drug, with a subsequent risk of withdrawal symptoms, has been reported for many classes of psychotropic drugs. Technically, withdrawal should be considered a side effect. The probability and severity of these reactions are remote with most drugs and more common with others. As a general rule, the more abruptly a drug is stopped and the shorter its elimination half-life, the more likely it is that clinically significant withdrawal symptoms will occur. When using some short-acting drugs, withdrawal reactions can result from missed doses and during daily intervals between doses. Gradual tapering of medications after prolonged use is recommended whenever possible. Although this reduces the risk of withdrawal reactions, it does not ensure they will not occur. So-called sedative hypnotics and opiates are the agents most often associated with mentally and physically distressing discontinuation reactions. In some cases, such as barbiturate use, withdrawal can be fatal.

Marked differences are found among agents, even within a given class, with respect to the probability and severity of discontinuation effects. For example, among the benzodiazepines, alprazolam and triazolam (Halcion) commonly produce more immediate and intense withdrawal symptoms than other compounds. Among the SSRIs, there is a well-described withdrawal syndrome that appears to be more frequent and severe with paroxetine (Paxil). It can, however, occur with any SSRI. Even fluoxetine can be associated with discontinuation symptoms, but the symptoms may be delayed and attenuated because of the long elimination half-life of its active metabolite. These manifestations are subtle and are delayed for weeks after the last dose. Venlafaxine also produces a severe SSRI-like withdrawal syndrome.

In addition to half-life, many variables can influence the likelihood and degree of discontinuation symptoms. Changes in the rate of drug metabolism, as an example, can play a role. Paroxetine is primarily metabolized by the cytochrome P450 (CYP) 2D6 isoenzyme, however, it is also a potent inhibitor of CYP 2D6. This results in autoinhibition, a dose-dependent inhibition of its own metabolism, with a subsequent increase in plasma concentrations of paroxetine. If the dose of paroxetine is decreased or the drug is stopped, the decline in its plasma concentrations can be steep, causing withdrawal to occur. Withdrawal can occur in rare cases in which the dose of a drug is not decreased, but a second agent, which had been inhibiting its metabolism, was stopped. For example, alprazolam is metabolized via the CYP 3A3/4 enzyme system. Nefazodone inhibits that enzyme. If a patient taking both agents for several weeks
discontinues the nefazodone, it could result in a rapid increase in the rate of alprazolam metabolism and a consequent drop in plasma concentrations.

The development of sustained-release versions of drugs, such as alprazolam, paroxetine, and venlafaxine, has not reduced the severity of their withdrawal reactions. The prolonged half-life of those agents results from delayed absorption rather than prolongation of the elimination phase. The frequency of drug dosing is reduced but not the rate of falloff in plasma concentrations.

Poor bioavailability with a generic agent may account for unexpected loss of clinical effect in emergence of withdrawal symptoms. The occurrence of these events soon after refilling a prescription should prompt examination of the new medication. It should be confirmed whether the dispensed medication and dose are both correct. It is difficult to ascertain whether generic medications are truly equivalent, so the possibility exists that differences in potency may underlie adverse changes in clinical status.

Withdrawal symptoms invariably occur hours or days after dose reduction or discontinuation. Symptoms resolve within a few weeks, so the persistence of symptoms argues against withdrawal. Although depletion studies have been shown to provoke rapid return of symptoms, in clinical practice, psychotic and mood symptoms do not usually reappear abruptly after long-term treatment.

COMBINATION OF DRUGS

According to the American Psychiatric Association Practice Guidelines for the Treatment of Psychiatric Disorders, “the use of multiple agents should be avoided if possible” in the treatment of psychiatric disorders. Although monotherapy represents the ideal, polypharmacy, the simultaneous use of psychotropic medications, has been commonplace since chlorpromazine was combined with reserpine (Diupres) in the early 1950s. The practice of combining drugs and the merits of various augmentation or combination strategies are routinely discussed in the literature and at scientific meetings. The mean number of simultaneously prescribed medications has increased in recent decades. Among psychiatric inpatients, the mean number of psychotropics prescribed is approximately three. Fixed combinations—drugs that contain more than one active ingredient—have been successfully marketed in the past, and research on new combinations is ongoing. A fluoxetine-olanzapine fixed combination has been approved as a treatment for bipolar disorder. The use of such drugs may increase the patients’ compliance by simplifying the drug regimen. A problem with combination drugs, however, is that the clinician has less flexibility in adjusting the dosage of one of the components; that is, the use of combination drugs can cause two drugs to be administered when only one drug continues to be necessary for therapeutic efficacy (Table 29.1-3).

Table 29.1-3
Combination Drugs Used in Psychiatry
Sometimes distinctions are made between augmentation and combination therapy. When two psychotropics with the same approved indications are used concurrently, this is termed combination therapy. Adding a drug with another indication is termed augmentation. Augmentation often entails use of a drug that is not primarily considered a psychotropic. For example, in treating depression, it is not common to add thyroid hormone to an approved antidepressant.

Almost all patients with bipolar disorder are taking more than one psychotropic agent. Combination treatment with drugs that treat depression and dopamine receptor antagonist or serotonin-dopamine antagonist has long been held as preferable in patients with psychotic depression. Similarly, SSRIs typically produce partial improvement in patients with OCD, so the addition of a serotonin-dopamine antagonist may be helpful.

Medications also can be combined to counteract side effects, to treat specific symptoms, and as a temporary measure to transition from one drug to another. It is common practice to add a new medication without the discontinuation of a prior drug, particularly when the first drug has provided partial benefit. This can be done as part of a plan to transition from an agent that is not producing a satisfactory response or as an attempt to maintain the patient on combined therapy.

Advantages of combining drugs include building on existing response, which may be less demoralizing, and the possibility that combinations produce new mechanisms that no single agent can provide. One limitation is that noncompliance and adverse effects increase, and the clinician may not be able to determine whether it was the second drug alone or the combination of drugs that resulted in a therapeutic success or a particular adverse effect. Combining drugs can create a broad spectrum effect and also changes the ratio of metabolites.

### COMBINED PSYCHOTHERAPY AND PHARMACOTHERAPY
Many psychiatrists believe that patients are best treated with a combination of medication and psychotherapy. Studies have demonstrated that the results of combined therapy are superior to those of either type of therapy alone. When pharmacotherapy and psychotherapy are used together, the approach should be coordinated, integrated, and synergistic. If the psychotherapy and the pharmacotherapy are directed by two separate clinicians, the clinicians must communicate with each other clearly and often.

**SPECIAL POPULATIONS**

Although every patient brings a unique combination of demographic and clinical variables to the clinical setting, certain patient populations require special consideration. When treating the young, the elderly, those with medical disorders, and women who want to conceive, are pregnant, or are nursing, awareness of risks associated with medication assumes increased importance. Data derived from clinical trials are of limited value in guiding many decisions, because populations in these studies consisted of healthy young adults and, until recently, excluded many women of child-bearing age. Studies of children and adolescents have become more common, so understanding of treatment effects in this population has grown.

**Children**

Understanding of the safety and efficacy of most psychotropic drugs when used to treat children is based more on clinical experience than on evidence from large clinical trial data. Other than attention-deficit/hyperactivity disorder (ADHD) and OCD, commonly used psychotropic drugs have no labeling for pediatric use, so results from adult studies are extrapolated to children. This is not necessarily appropriate because of developmental differences in pharmacokinetics and pharmacodynamics. Dosing is another special consideration in drug use with children. Although the small volume of distribution suggests the use of lower doses than those used in adults, a child’s higher rate of metabolism suggests that a higher ratio of milligrams of drug to kilograms of body weight should be used. In practice, it is best to begin with a small dose and to increase it until clinical effects are observed. The clinician should not hesitate, however, to use adult dosages in children if these dosages are effective and the adverse effects are acceptable.

The paucity of research data is a legacy of many years in which manufacturers avoided conducting trials in children because of liability concerns, small market share, and, hence, limited profit potential represented by this population. To correct this problem, the FDA Modernization Act (FDAMA) of 1997 provided for special encouragement and incentives to study drugs for pediatric use.

**Pregnant and Nursing Women**

No definitive assurances exist that any drug is completely without risk during pregnancy and lactation. No psychotropic medication is absolutely contraindicated during
pregnancy, although drugs with known risks of birth defects, premature birth, or neonatal complications should be avoided if acceptable alternatives are available.

Women who are pregnant or lactating are excluded from clinical trials, and it is only recently that women of child-bearing age have been able to participate in these studies. As a result, there are large gaps in knowledge of the effects of psychotropic agents on the developing fetus and on the neonate. Most of what is known is the result of anecdotal reports or data from registries. The basic rule is to avoid administering any drug to a woman who is pregnant (particularly during the first trimester) or who is breast-feeding a child, unless the mother’s psychiatric disorder is severe and it is determined that the therapeutic value of the drug outweighs the theoretical adverse effects on the fetus or newborn. A woman may elect to continue on medication, because she does not want to chance a possible recurrence of painful or disabling symptoms.

Among the newer antidepressants, paroxetine is the only one to carry a warning from the FDA, the result of an increased risk of cardiac malformation. The agents with the most well-documented risk of specific birth defects are lithium, carbamazepine, and valproate. Lithium administration during pregnancy is associated with Ebstein’s anomaly, a serious abnormality in cardiac development, although recent evidence suggests that the risk is not as great as previously believed. Carbamazepine and valproic acid are associated with neural tube defects, which can be prevented by use of folate during pregnancy. Lamotrigine may cause oral clefts when used during the first trimester. Some experts advise that all women of child-bearing age who are treated with psychotropics take supplemental folate.

The administration of psychotherapeutic drugs at or near delivery can cause the baby to be overly sedated at delivery, thus requiring a respirator, or to be physically dependent on the drug, requiring detoxification and the treatment of a withdrawal syndrome. Reports exist of a neonatal withdrawal syndrome associated with third trimester use of SSRIs in pregnant women. They have also been implicated in producing pulmonary hypertension in newborns.

Virtually all psychiatric drugs are secreted in the milk of a nursing mother; therefore, mothers on those agents should be advised not to breast-feed their infants.

**Elderly Patients**

The two major concerns when treating geriatric patients with psychotherapeutic drugs are that elderly persons may be more susceptible to adverse effects (particularly cardiac effects) and may metabolize and excrete drugs more slowly, thus requiring lower dosages of medication. In practice, clinicians should begin treating geriatric patients with a small dose, usually approximately half of the usual starting dose. The dose should be raised in small increments, more slowly than for middle-aged adults, until a clinical benefit is achieved or unacceptable adverse effects appear. Although many geriatric patients require a small dose of medication, many others require a full therapeutic dose.

Elderly patients account for approximately one third of all prescription drug use and a substantial percentage of over-the-counter preparations as well. Even more significant
is the incidence of polypharmacy. Recent surveys have found that elderly patients in the community are taking between three and five medications, and that hospitalized elderly patients are treated with an average of ten drugs. Nearly half of all patients in long-term care facilities are prescribed one or more psychotropic agents. In view of these statistics, clinicians need to consider potential types and likelihood of drug interactions when selecting medications.

Psychotropic drugs have been shown to be causally related to falls in the elderly. Discontinuation of psychotropic drugs results in an estimated 40 percent risk reduction for falls. This association between psychotropics and falls and hip fractures may weaken as newer agents become widely used. As a rule, new-generation compounds produce less unwanted sedation, dizziness, parkinsonism, and postural hypotension.

Age-related changes in renal clearance and hepatic metabolism make it more important to be conservative with the starting doses of medication as well as the rate of dose titration. Within any class of psychotropic agents, those with potentially serious consequences, such as hypotension, cardiac conduction abnormalities, anticholinergic activity, and respiratory depression, are not suitable choices. Drugs that cause cognitive impairment, such as benzodiazepines and anticholinergics, can mimic or exacerbate symptoms of dementia. Similarly, dopamine receptor antagonists can worsen or induce Parkinson’s disease, another age-related disorder. Some side effects, such as SSRI-associated syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and oxcarbazepine-associated hyponatremia, occur more commonly in older patients.

A common ethical dilemma with the medically ill elderly or those with dementia is the question of their capacity to give informed consent before treatment with psychotropic drugs or electroconvulsive therapy (ECT).

**Medically Ill Patients**

There are special considerations, diagnostic and therapeutic, when administering psychiatric drugs to medically ill patients. The medical disorder should be ruled out as a cause of the psychiatric symptoms. For example, patients with neurological or endocrine disorders or those infected with human immunodeficiency virus (HIV) may experience disturbances of mood and cognition. Common medications, such as corticosteroids and l-dopa, are associated with induction of mania.

A patient with diabetes mellitus is better treated with an agent without the risk of weight gain or glucose dysregulation. Depending on the diagnosis, drugs that might treat the primary psychiatric disorder and also cause weight loss, drugs such as bupropion, topiramate, and zonisamide, should be prescribed for these patients. Patients with obstructive pulmonary disease should not be given sedating drugs, which raise the arousal threshold and suppress respiration. Patients with medical disorders are also taking other medications, which can result in pharmacodynamic and pharmacokinetic interactions. Combined treatment with an inducer of multiple CYP enzymes and a drug that is a substrate for those enzymes could result in subtherapeutic levels, leading to inadequate symptom control. Use of the tuberculosis treatment rifampicin (Rifadin) with
carbamazepine is an example of this. Use of drugs that inhibit CYP 2D6, agents such as paroxetine and fluoxetine, can prevent the conversion of hydrocodone (Robidone) and other opiates into an active analgesic form. NSAIDs are also a rare cause of perceptual disturbances and psychotic symptoms.

Other issues include a potentially increased sensitivity to adverse effects, including increased or decreased metabolism and excretion of the drug, and interactions with other medications. Drug interactions are an obvious concern when drugs with a narrow therapeutic range are being used. Any change in the rate of metabolism or interference with the formation and elimination of metabolites can profoundly influence the activity of that drug. Similarly, interactions that interfere with drug metabolism can produce an increase in side effects and toxicity.

As with children and geriatric patients, the most reasonable clinical practice is to begin with a small dosage, to increase it slowly, and to watch for clinical benefit and adverse effects. Determining the plasma drug concentrations may be helpful for such patients, but therapeutic blood concentrations for most psychotropic drugs are neither necessary nor routinely available.

Substance Abuse

Many patients who seek or need treatment for a psychiatric disorder engage in chronic use of illicit substances or drink excessive amounts of alcohol. Marijuana is the most commonly used illicit (in most states) drug in the United States.

Discontinuation of chronic drug or alcohol use can result not only in craving, but also in clinically significant psychiatric and physiological withdrawal symptoms. For many patients, successful treatment of their underlying psychiatric disorder may not be possible in the presence of ongoing marijuana, cocaine, and alcohol use. If several trials of medications fail, hospitalization for detoxification may be necessary. Little research and no consensus exist about how to use psychotropic agents in patients who are regular users of cocaine, marijuana, or other recreational drugs.

REGULATORY ISSUES

The FDA has the authority to approve a drug for clinical use and to ensure that product labeling is truthful and contains all information pertinent to the safe and effective use of that drug.

Product information that is FDA approved for marketed drugs appears as a package insert that lists potential side effects, drug interactions, the need for special monitoring, and restrictions for use. In some cases, these adverse reactions and potential safety hazards warrant a special warning label called a black box label. The FDA typically negotiates final labeling language with the company; however, in cases where a company refuses to satisfy the FDA, the agency may initiate proceedings to remove the drug from clinical use. In recent years, warning labels have been applied to entire classes of psychotropic drugs, including the serotonin dopamine antagonists and antidepressants such as the SSRIs.
The product information may also contain a “Contraindications” heading. This section describes instances in which the drug should not be used because the risk of using it clearly outweighs the benefit. If no contraindications are known, this section of the labeling will state “None known.”

A precautions section may contain precautions for most individuals taking the drug, as well as for specific groups, such as pregnant women, nursing mothers, or children. In this section, one will find recommendations for patients to ensure safe and effective use of the drug. For example, there may be precautions about driving when taking the medication or using substances such as other drugs, food, or alcohol that may have harmful effects if taken while using the medication. The Precautions section also provides information about laboratory tests needed to track responses or to identify adverse reactions to the drug or about known interactions with other drugs, foods, or ingredients.

Every product label has an Adverse Reaction section that lists the frequency of undesirable effects that may be associated with use of a drug. Causes of adverse reactions can include medication errors, such as overdosage, or interactions between different drugs or between drugs and certain foods.

**NONAPPROVED DOSAGES AND USES**

It is now common practice to treat psychiatric disorders with drugs that are approved for nonpsychiatric conditions. Some examples include propranolol (Inderal) for social anxiety and treatment of lithium-induced tremor; verapamil (Calan, Isoptin) for mania and treatment of MAOI-induced hypertensive crisis; levothyroxine (Levoxyl) for antidepressant augmentation; clonidine (Catapres) and guanfacine (Tenex) for ADHD and posttraumatic stress disorder (PTSD); dextroamphetamine (Dexedrine) for antidepressant augmentation; and riluzole (Rilutek) for self-injurious behavior. Off-label use of a drug is not a violation of law or a departure from good medical practice. The FDA does not limit the manner in which a physician may use an approved drug. Medications can be prescribed for any reason shown to be medically indicated for the welfare of the patient. Once a drug is approved for commercial use, a physician can, as part of the practice of medicine, lawfully prescribe a different dosage for a patient or may otherwise vary the conditions of use from what is approved in the package labeling without notifying the FDA or obtaining its approval.

Failure to follow the information on the drug label does not in itself impose liability and should not preclude a physician from using good clinical judgment in the service of the patient. Physicians are permitted to use a drug for indications not included on the drug’s official labeling without violating the FDA rules. This fact, however, does not absolve the physician of responsibility for an untoward result from treatment. Patients can still sue for possible medical malpractice with the reasoning that the failure to follow the FDA-approved label can be interpreted as deviating from the prevailing standard of care.

When using a drug for an unapproved indication or in a dose outside the usual range,
good clinical practice is to explain to the patient and to document in the chart why a drug is being used instead of an approved agent. In cases of doubt about a plan to use a drug off label, a consultation with a colleague should be obtained.

In some cases, a drug has obtained a limited approval for an indication. Divalproex (Depakote), quetiapine (Seroquel), and risperidone, for example, are approved by the FDA for the acute, but not long-term, treatment of mania. Nevertheless, these drugs are routinely used for long-term prevention of recurrences of mania and bipolar disorder. In the case of lamotrigine, it was accepted as a first-choice agent for the treatment of bipolar disorder long before the FDA granted approval for that indication.

PLACEBOS

Pharmacologically inactive substances have long been known to sometimes produce significant clinical benefits. A patient who believes that a compound is helpful may often derive considerable benefit from taking that substance, whether it is known to be pharmacologically active or not. For many psychiatric disorders, including mild to moderate depression and some anxiety disorders, well over 30 percent of patients can exhibit significant improvement or remission of symptoms on a placebo. For other conditions, such as schizophrenia, manic episodes, and psychotic depression, the placebo response rate is very low. Whereas suggestion is undoubtedly important in the efficacy of placebos (and active drugs), placebos can produce biological effects. For example, placebo-induced analgesia may sometimes be blocked by naloxone (Narcan), which suggests that endorphins may mediate the analgesia derived from taking a placebo. It is conceivable that placebos may also stimulate endogenous anxiolytic and antidepressant factors, resulting in clinical improvement in patients with depression and anxiety disorders.

Just as placebos can produce benefit, they can also have adverse effects. In many studies, some adverse effects are likely to be more common with placebos than with the active drug. Some patients will not tolerate placebos despite the fact that they are supposedly inert, and they exhibit adverse effects (called the nocebo phenomenon). It is easy to discount such patients as overly suggestible; however, if beneficial endogenous factors can be stimulated by placebos, perhaps toxic endogenous factors can also be produced.

Prudence is needed in contemplating the use of a placebo in clinical practice. Treating a patient with a placebo without consent can seriously undermine a patient’s confidence in the physician if, and when, it is discovered.

REFERENCES

29.2 Medication-Induced Movement Disorders

Medication-induced movement disorders are commonly associated with the use of psychotropic drugs. Although most frequently associated with drugs that block dopamine type 2 (D₂) receptors, abnormal motor activity may occur with other types of medications as well. Sometimes it can be difficult to determine if abnormal motor movements are an adverse event or a symptom of an underlying disorder. For example, anxiety can resemble akathisia, and alcohol or benzodiazepine withdrawal can cause tremor. The American Psychiatric Association has decided to retain the term neuroleptic when discussing side effects associated with drugs used to treat psychosis—the dopamine receptor antagonists (DRAs) and second-generation antipsychotics (SGAs). The rationale for continued use of the term is that it was originally used to describe the tendency of
these drugs to cause abnormal movements.

The most common neuroleptic-related movement disorders are parkinsonism, acute dystonia, and acute akathisia. Neuroleptic malignant syndrome is a life-threatening and often misdiagnosed condition. Neuroleptic-induced tardive dyskinesia is a late-appearing adverse effect of neuroleptic drugs and can be irreversible; recent data, however, indicate that the syndrome, although still serious and potentially disabling, is less pernicious than was previously thought in patients taking DRAs. The newer antipsychotics, the serotonin-dopamine antagonists (SDAs), block binding to dopamine receptors to a much lesser degree and thereby are presumed to be less likely to produce such movement disorders. Nevertheless, this risk remains and vigilance is still required when these drugs are prescribed.

Table 29.2-1 lists the selected medications associated with movement disorders and their impact on relevant neurotransmitters.

</table>
Symptoms of neuroleptic-induced parkinsonism and other medication-induced parkinsonism include muscle stiffness (lead pipe rigidity), cogwheel rigidity, shuffling gait, stooped posture, and drooling. The pill-rolling tremor of idiopathic parkinsonism is rare, but a regular, coarse tremor similar to essential tremor may be present. The so-called *rabbit syndrome*, a tremor affecting the lips and perioral muscles, is another parkinsonian effect seen with antipsychotics, although perioral tremor is more likely than other tremors to occur late in the course of treatment.

**Epidemiology**

Parkinsonian adverse effects typically occur within 5 to 90 days of the initiation of treatment. Patients who are elderly and female are at the highest risk for neuroleptic-induced parkinsonism, although the disorder can occur at all ages.

**Etiology**

Neuroleptic-induced parkinsonism is caused by the blockade of D$_2$ receptors in the caudate at the termination of the nigrostriatal dopamine neurons. All antipsychotics can cause the symptoms, especially high-potency drugs with low levels of anticholinergic activity, most notably haloperidol (Haldol).

**Differential Diagnosis**

Included in the differential diagnosis are idiopathic parkinsonism, other organic causes of parkinsonism, and depression, which can also be associated with parkinsonian symptoms. Decreased psychomotor activity and blunted facial expression are symptoms of depression and idiopathic parkinsonism.

**Treatment**

Parkinsonism can be treated with anticholinergic agents, benztropine (Cogentin), amantadine (Symmetrel), or diphenhydramine (Benadryl) (Table 29.2-2). Anticholinergics should be withdrawn after 4 to 6 weeks to assess whether tolerance to the parkinsonian effects has developed; about half of patients with neuroleptic-induced parkinsonism require continued treatment. Even after the antipsychotics are withdrawn, parkinsonian symptoms can last up to 2 weeks and even up to 3 months in elderly patients. With such patients, the clinician may continue the anticholinergic drug after the antipsychotic has been stopped until the parkinsonian symptoms resolve completely.

| **Drug Treatment of Extrapyramidal Disorders** |
NEUROLEPTIC MALIGNANT SYNDROME

Diagnosis, Signs, and Symptoms

Neuroleptic malignant syndrome is a life-threatening complication that can occur anytime during the course of antipsychotic treatment. The motor and behavioral symptoms include muscular rigidity and dystonia, akinesia, mutism, obtundation, and agitation. The autonomic symptoms include hyperthermia, diaphoresis, and increased pulse and blood pressure. Laboratory findings include an increased white blood cell count and increased levels of creatinine phosphokinase, liver enzymes, plasma myoglobin, and myoglobinuria, occasionally associated with renal failure.

Epidemiology

About 0.01 to 0.02 percent of patients treated with antipsychotics develop neuroleptic malignant syndrome. Men are affected more frequently than women, and young patients are affected more commonly than elderly patients. The mortality rate can reach 10 to 20 percent or even higher when depot antipsychotic medications are involved.

Course and Prognosis

The symptoms usually evolve over 24 to 72 hours, and the untreated syndrome lasts 10 to 14 days. The diagnosis is often missed in the early stages, and the withdrawal or agitation may mistakenly be considered to reflect an exacerbation of the psychosis.

Treatment

In addition to supportive medical treatment, the most commonly used medications for

the condition are dantrolene (Dantrium) and bromocriptine (Parlodel), although amantadine (Symmetrel) is sometimes used (Table 29.2-3). Bromocriptine and amantadine pose direct DRA effects and may serve to overcome the antipsychotic-induced dopamine receptor blockade. The lowest effective dosage of the antipsychotic drug should be used to reduce the chance of neuroleptic malignant syndrome. High-potency drugs, such as haloperidol, pose the greatest risk. Antipsychotic drugs with anticholinergic effects seem less likely to cause neuroleptic malignant syndrome. Electroconvulsive therapy (ECT) has been used.

**MEDICATION-INDUCED ACUTE DYSTONIA**

**Diagnosis, Signs, and Symptoms**

*Dystonias* are brief or prolonged contractions of muscles that result in obviously abnormal movements or postures, including oculogyric crises, tongue protrusion, trismus, torticollis, laryngeal–pharyngeal dystonias, and dystonic postures of the limbs and trunk. Other dystonias include blepharospasm and glosopharyngeal dystonia; the latter results in dysarthria, dysphagia, and even difficulty in breathing, which can cause cyanosis. Children are particularly likely to evidence opisthotonos, scoliosis, lordosis, and writhing movements. Dystonia can be painful and frightening and often results in noncompliance with future drug treatment regimens.

**Epidemiology**

The development of acute dystonic symptoms is characterized by their early onset during the course of treatment with neuroleptics. There is a higher incidence of acute dystonia in men, in patients younger than age 30 years, and in patients given high dosages of high-potency medications.
Etiology
Although it is most common with intramuscular doses of high-potency antipsychotics, dystonia can occur with any antipsychotic. The mechanism of action is thought to be dopaminergic hyperactivity in the basal ganglia that occurs when central nervous system (CNS) levels of the antipsychotic drug begin to fall between doses.

Differential Diagnosis
The differential diagnosis includes seizures and tardive dyskinesia.

Course and Prognosis
Dystonia can fluctuate spontaneously and respond to reassurance, so the clinician gets the false impression that the movement is hysterical or completely under conscious control.

Treatment
Prophylaxis with anticholinergics or related drugs (outlined in Table 29.2-2) usually prevents dystonia, although the risks of prophylactic treatment weigh against that benefit. Treatment with intramuscular anticholinergics or intravenous or intramuscular diphenhydramine (Benadryl) (50 mg) almost always relieves the symptoms. Diazepam (Valium) (10 mg intravenously), amobarbital (Amytal), caffeine sodium benzoate, and hypnosis have also been reported to be effective. Although tolerance for the adverse effects usually develops, it is prudent to change the antipsychotic if the patient is particularly concerned that the reaction may recur.

MEDICATION-INDUCED ACUTE AKATHISIA

Diagnosis, Signs, and Symptoms
Akathisia is subjective feelings of restlessness, objective signs of restlessness, or both. Examples include a sense of anxiety, inability to relax, jitteriness, pacing, rocking motions while sitting, and rapid alternation of sitting and standing. Akathisia has been associated with the use of a wide range of psychiatric drugs, including antipsychotics, antidepressants, and sympathomimetics. Once akathisia is recognized and diagnosed, the antipsychotic dose should be reduced to the minimal effective level. Akathisia may be associated with a poor treatment outcome.

Epidemiology
Middle-aged women are at increased risk of akathisia, and the time course is similar to that for neuroleptic-induced parkinsonism.

Treatment
Three basic steps in the treatment of akathisia are reducing medication dosage, attempting treatment with appropriate drugs, and considering changing the neuroleptic. The most efficacious drugs are β-adrenergic receptor antagonists, although anticholinergic drugs, benzodiazepines, and cyproheptadine (Periactin) may benefit some patients. In some cases of akathisia, no treatment seems to be effective.

TARDIVE DYSKINESIA

Diagnosis, Signs, and Symptoms

*Tardive dyskinesia* is a delayed effect of antipsychotics; it rarely occurs until after 6 months of treatment. The disorder consists of abnormal, involuntary, irregular choreoathetoid movements of the muscles of the head, limbs, and trunk. The severity of the movements ranges from minimal—often missed by patients and their families—to grossly incapacitating. Perioral movements are the most common and include darting, twisting, and protruding movements of the tongue; chewing and lateral jaw movements; lip puckering; and facial grimacing. Finger movements and hand clenching are also common. Torticollis, retrocollis, trunk twisting, and pelvic thrusting occur in severe cases. In the most serious cases, patients may have breathing and swallowing irregularities that result in aerophagia, belching, and grunting. Respiratory dyskinesia has also been reported. Dyskinesia is exacerbated by stress and disappears during sleep.

Epidemiology

Tardive dyskinesia develops in about 10 to 20 percent of patients who are treated for more than a year. About 20 to 40 percent of patients who require long-term hospitalization have tardive dyskinesia. Women are more likely to be affected than men. Children, patients who are more than 50 years of age, and patients with brain damage or mood disorders are also at high risk.

Course and Prognosis

Between 5 and 40 percent of all cases of tardive dyskinesia eventually remit, and between 50 and 90 percent of all mild cases remit. Tardive dyskinesia is less likely to remit in elderly patients than in young patients, however.

Treatment

The three basic approaches to tardive dyskinesia are prevention, diagnosis, and management. Prevention is best achieved by using antipsychotic medications only when clearly indicated and in the lowest effective doses. The atypical antipsychotics are associated with less tardive dyskinesia than the older antipsychotics. Clozapine (Clozaril) is the only antipsychotic to have minimal risk of tardive dyskinesia and can even help improve preexisting symptoms of tardive dyskinesia. This has been attributed to its low affinity for D₂ receptors and high affinity for 5-hydroxytryptamine (5-HT)
receptor antagonism. Patients who are receiving antipsychotics should be examined regularly for the appearance of abnormal movements, preferably with the use of a standardized rating scale (Table 29.2-4). Patients frequently experience an exacerbation of their symptoms when the DRA is withheld, whereas substitution of an SDA may limit the abnormal movements without worsening the progression of the dyskinesia.

**Table 29.2-4**

**Abnormal Involuntary Movement Scale (AIMS) Examination Procedure**

</tr>
</tbody>
</table>

Once tardive dyskinesia is recognized, the clinician should consider reducing the dose of the antipsychotic or even stopping the medication altogether. Alternatively, the clinician may switch the patient to clozapine or to one of the new SDAs. In patients who cannot continue taking any antipsychotic medication, lithium (Eskalith), carbamazepine (Tegretol), or benzodiazepines may effectively reduce the symptoms of both the movement disorder and the psychosis.

**TARDIVE DYSTONIA AND TARDIVE AKATHISIA**

On occasion, dystonia and akathisia emerge late in the course of treatment. These symptoms may persist for months or years despite drug discontinuation or dose reduction.

**MEDICATION-INDUCED POSTURAL TREMOR**

**Diagnosis, Signs, and Symptoms**

*Tremor* is a rhythmic alteration in movement that is usually faster than one beat per
second. Fine tremor (8 to 12 Hz) is most common.

**Epidemiology**
Typically, tremors decrease during periods of relaxation and sleep and increase with stress or anxiety.

**Etiology**
Whereas all the above diagnoses specifically include an association with a neuroleptic, a range of psychiatric medications can produce tremor—most notably, lithium, stimulants, antidepressants, caffeine, and valproate (Depakene).

**Treatment**
The treatment involves four principles:
1. The lowest possible dose of the psychiatric drug should be taken.
2. Patients should minimize caffeine consumption.
3. The psychiatric drug should be taken at bedtime to minimize the amount of daytime tremor.
4. β-adrenergic receptor antagonists (e.g., propranolol [Inderal]) can be given to treat drug-induced tremors.

**OTHER MEDICATION-INDUCED MOVEMENT DISORDERS**

**Nocturnal Myoclonus**
*Nocturnal myoclonus* consists of highly stereotyped, abrupt contractions of certain leg muscles during sleep. Patients lack any subjective awareness of the leg jerks. The condition may be present in about 40 percent of persons over 65 years of age. The cause is unknown, but it is a rare side effect of selective serotonin reuptake inhibitors (SSRIs).

The repetitive leg movements occur every 20 to 60 seconds, with extensions of the large toe and flexion of the ankle, the knee, and the hips. Frequent awakenings, unrefreshing sleep, and daytime sleepiness are major symptoms. No treatment for nocturnal myoclonus is universally effective. Treatments that may be useful include benzodiazepines, levodopa (Larodopa), quinine, and, in rare cases, opioids.

**Restless Leg Syndrome**
In *restless leg syndrome*, persons feel deep sensations of creeping inside the calves whenever sitting or lying down. The dysesthesias are rarely painful but are agonizingly relentless and cause an almost irresistible urge to move the legs; thus, this syndrome interferes with sleep and with falling asleep. It peaks in middle age and occurs in 5 percent of the population. The cause is unknown, but it is a rare side effect of SSRIs.
Symptoms are relieved by movement and by leg massage. The dopamine receptor agonists ropinirole (Requip) and pramipexole (Mirapex) are effective in treating this syndrome. Other treatments include the benzodiazepines, levodopa, quinine, opioids, propranolol, valproate, and carbamazepine.

HYPERTHERMIC SYNDROMES

All the medication-induced movement disorders may be associated with hyperthermia. Table 29.2-5 lists the various conditions associated with hyperthermia.

29.3 α2-Adrenergic Receptor Agonists, α1-Adrenergic Receptor Antagonists: Clonidine, Guanfacine, Prazosin, and Yohimbine

Clonidine (Catapres) was developed initially as an antihypertensive medication because of its noradrenergic effects. It is an α2-adrenergic receptor agonist and reduces plasma norepinephrine. It has been studied in many neurologic and psychiatric conditions, including attention-deficit/hyperactivity disorder (ADHD), tic disorders, opiates and alcohol withdrawal, and posttraumatic stress disorder (PTSD). Its use has been somewhat limited by sedation and hypotension, which are common, and in children, its use is limited by its cardiac effects. Guanfacine (Tenex), another α2-adrenergic receptor agonist, has been preferentially used because of its differential affinity for certain α2-adrenergic receptor subtypes, resulting in less sedation and hypotension. However, there have been fewer clinical studies of guanfacine than of clonidine.

Prazosin (Minipress) is an α1-postsynaptic antagonist. It reduces blood pressure (BP) through vasodilation. Prazosin has shown benefits in treating sleep disorders associated with PTSD.

CLONIDINE AND GUANFACINE

Pharmacologic Actions

Guanfacine is an agonist on presynaptic α2-receptors. It inhibits sympathetic outflow and causes vasodilation of blood vessels. It is marketed as a treatment for high BP. It is more selective and less potent than clonidine, the other widely used α2-agonist. Clonidine and guanfacine are well absorbed from the gastrointestinal tract and reach peak plasma levels 1 to 3 hours after oral administration. The half-life of clonidine is 6 to 20 hours and that of guanfacine is 10 to 30 hours.

The agonist effects of clonidine and guanfacine on presynaptic α2-adrenergic receptors in the sympathetic nuclei of the brain result in a decrease in the amount of norepinephrine released from the presynaptic nerve terminals. This serves generally to reset the body’s sympathetic tone at a lower level and decrease arousal.

Therapeutic Indications

There is considerably more experience in clinical psychiatry with clonidine than with guanfacine. There is recent interest in the use of guanfacine for the same indications.
Withdrawal from Opioids, Alcohol, Benzodiazepines, or Nicotine.
Clonidine and guanfacine are effective in reducing the autonomic symptoms of rapid opioid withdrawal (e.g., hypertension, tachycardia, dilated pupils, sweating, lacrimation, and rhinorrhea) but not the associated subjective sensations. Clonidine administration (0.1 to 0.2 mg two to four times a day) is initiated before detoxification and is then tapered off over 1 to 2 weeks (Table 29.3-1).

| Clonidine 0.1–0.2 mg PO four times a day: hold for systolic BP <90 mm Hg or bradycardia; stabilize for 2–3 days, then taper over 5–10 days: OR
| Clonidine 0.1–0.2 mg PO q4–6h as needed for withdrawal signs or symptoms; stabilize for 2–3 days, then taper over 5–10 days OR Test dose with clonidine 0.1–0.2 mg PO or SL (for patients weighing over 200 lbs); check BP after 1 hr. If diastolic BP >70 mm Hg and no symptoms of hypotension, begin treatment as follows:
| Weight (lb) | Number of Clonidine Patches
| <110 | 1 patch
| 110–160 | 2 patches
| 160–200 | 2 patches
| >200 | 2 patches

BP, blood pressure; PO, oral; q, every; SL, sublingual. TTS, through the skin.

Clonidine and guanfacine can reduce symptoms of alcohol and benzodiazepine withdrawal, including anxiety, diarrhea, and tachycardia. They can reduce craving, anxiety, and the irritability symptoms of nicotine withdrawal. The transdermal patch formulation of clonidine is associated with better long-term compliance for purposes of detoxification than is the tablet formulation.

Tourette’s Disorder. Clonidine and guanfacine are effective drugs for the treatment of Tourette’s disorder. Most clinicians begin treatment for Tourette’s disorder
with the standard dopamine receptor antagonists haloperidol (Haldol) and pimozide (Orap) and the serotonin-dopamine antagonists risperidone (Risperdal) and olanzapine (Zyprexa). However, if concerned about the adverse effects of these drugs, the clinician may begin treatment with clonidine or guanfacine. The starting dose of clonidine for children is 0.05 mg a day; it can be increased to 0.3 mg a day in divided doses. Up to 3 months are needed before the beneficial effects of clonidine can be seen in patients with Tourette’s disorder. The response rate has been reported to be up to 70 percent.

**Other Tic Disorders.** Clonidine and guanfacine reduce the frequency and severity of tics in persons with tic disorder with or without comorbid ADHD.

**Hyperactivity and Aggression in Children.** Clonidine and guanfacine can be useful alternatives for the treatment of ADHD. They are used in place of sympathomimetics and antidepressants, which may produce paradoxical worsening of hyperactivity in some children with intellectual disability, aggression, or features on the spectrum of autism. Clonidine and guanfacine can improve mood, reduce activity level, and improve social adaptation. Some impaired children may respond favorably to clonidine, but others may simply become sedated. The starting dose is 0.05 mg a day; it can be raised to 0.3 mg a day in divided doses. The efficacy of clonidine and guanfacine for control of hyperactivity and aggression often diminishes over several months of use.

Clonidine and guanfacine can be combined with methylphenidate (Ritalin) or dextroamphetamine (Dexedrine) to treat hyperactivity and inattentiveness, respectively. A small number of cases have been reported of sudden death of children taking clonidine together with methylphenidate; however, it has not been conclusively demonstrated that these medications contributed to these deaths. The clinician should explain to the family that the efficacy and safety of this combination have not been investigated in controlled trials. Periodic cardiovascular assessments, including vital signs and electrocardiograms, are warranted if this combination is used.

**Posttraumatic Stress Disorder.** Acute exacerbations of PTSD may be associated with hyperadrenergic symptoms such as hyperarousal, exaggerated startle response, insomnia, vivid nightmares, tachycardia, agitation, hypertension, and perspiration. Preliminary reports suggested that these symptoms may respond to the use of clonidine or, especially for overnight benefit, to the use of guanfacine. More recent studies have failed to demonstrate that guanfacine produces an improvement in PTSD symptoms.

**Other Disorders.** Other potential indications for clonidine include other anxiety disorders (panic disorder, phobias, obsessive-compulsive disorder, and generalized anxiety disorder) and mania, in which it may be synergistic with lithium (Eskalith) or carbamazepine (Tegretol). Anecdotal reports have noted the efficacy of clonidine in schizophrenia and tardive dyskinesia. A clonidine patch can reduce the hypersalivation and dysphagia caused by clozapine. Low-dose use has been reported effective in hallucinogen-persisting perceptive disorders.
Precautions and Adverse Reactions

The most common adverse effects associated with clonidine are dry mouth and eyes, fatigue, sedation, dizziness, nausea, hypotension, and constipation, which result in discontinuation of therapy by about 10 percent of all persons taking the drug. Some persons also experience sexual dysfunction. Tolerance may develop to these adverse effects. A similar but milder adverse profile is seen with guanfacine, especially in doses of 3 mg or more per day. Clonidine and guanfacine should not be taken by adults with BP below 90/60 mm Hg or with cardiac arrhythmias, especially bradycardia. Development of bradycardia warrants gradual, tapered discontinuation of the drug. Clonidine in particular is associated with sedation, and tolerance does not usually develop to this adverse effect. Uncommon central nervous system (CNS) adverse effects of clonidine include insomnia, anxiety, and depression; rare CNS adverse effects include vivid dreams, nightmares, and hallucinations. Fluid retention associated with clonidine treatment can be treated with diuretics.

The transdermal patch formulation of clonidine may cause local skin irritation, which can be minimized by rotating the sites of application.

Overdose. Persons who take an overdose of clonidine may present with coma and constricted pupils, symptoms similar to those of an opioid overdose. Other symptoms of overdose are decreased BP, pulse, and respiratory rate. Guanfacine overdose produces a milder version of these symptoms. Clonidine and guanfacine should be avoided during pregnancy and by nursing mothers. Elderly persons are more sensitive to the drug than are younger adults. Children are susceptible to the same adverse effects as are adults.

Withdrawal. Abrupt discontinuation of clonidine can cause anxiety, restlessness, perspiration, tremor, abdominal pain, palpitations, headache, and a dramatic increase in BP. These symptoms may appear about 20 hours after the last dose of clonidine, and these may also be seen if one or two doses are skipped. A similar set of symptoms occasionally occurs 2 to 4 days after discontinuation of guanfacine, but the usual course is gradual return to baseline BP over 2 to 4 days. Because of the possibility of discontinuation symptoms, doses of clonidine and guanfacine should be tapered slowly.

Drug Interactions

Clonidine and guanfacine cause sedation, especially early in therapy, and when administered with other centrally active depressants, such as barbiturates, alcohol, and benzodiazepines, the potential for additive sedative effects should be considered. Dose reduction may be required in patients receiving agents that interfere with atrioventricular (AV) node and sinus node conduction such as β-blockers, calcium channel blockers, and digitalis. This combination increases the risk of AV block and bradycardia. Clonidine should not be given with tricyclic antidepressants, which can inhibit the hypotensive effects of clonidine.
Laboratory Interferences

No known laboratory interferences are associated with the use of clonidine or guanfacine.

Dosage and Clinical Guidelines

Clonidine is available in 0.1-, 0.2-, and 0.3-mg tablets. The usual starting dosage is 0.1 mg orally twice a day; the dosage can be raised by 0.1 mg a day to an appropriate level (up to 1.2 mg per day). Clonidine must always be tapered when it is discontinued to avoid rebound hypertension, which may occur about 20 hours after the last clonidine dose. A weekly transdermal formulation of clonidine is available at doses of 0.1, 0.2, and 0.3 mg per day. The usual starting dosage is the 0.1-mg-a-day patch, which is changed each week for adults and every 5 days for children; the dose can be increased, as needed, every 1 to 2 weeks. Transition from the oral to the transdermal formulations should be accomplished gradually by overlapping them for 3 to 4 days.

Guanfacine is available in 1- and 2-mg tablets. The usual starting dosage is 1 mg before sleep, and this can be increased to 2 mg before sleep after 3 to 4 weeks, if necessary. Regardless of the indication for which clonidine or guanfacine is being used, the drug should be withheld if a person becomes hypotensive (BP below 90/60 mm Hg).

An extended-release preparation of guanfacine (Intuniv) is also available. Extended-release guanfacine should be dosed once daily. Tablets should not be crushed, chewed, or broken before swallowing because this will increase the rate of guanfacine release. It should not be administered with high fat meals due to increased exposure. The extended-release formulation should not be substituted for immediate-release guanfacine tablets on a milligram-per-milligram basis because of differing pharmacokinetic profiles. If switching from immediate-release guanfacine, discontinue that treatment, and titrate with extended-release guanfacine according to the following recommended schedule:

1. Begin at a dose of 1 mg/day, and adjust in increments of no more than 1 mg/week, for both monotherapy and adjunctive therapy to a psychostimulant.
2. Maintain the dose within the range of 1 to 4 mg once daily, depending on clinical response and tolerability, for both monotherapy and adjunctive therapy to a psychostimulant. In clinical trials, patients were randomized or dose optimized to doses of 1 mg, 2 mg, 3 mg, or 4 mg and received extended-release guanfacine once daily in the morning in monotherapy trials and once daily in the morning or the evening in the adjunctive therapy trial.
3. In monotherapy trials, clinically relevant improvements were observed beginning at doses in the range 0.05 to 0.08 mg/kg once daily. Efficacy increased with increasing weight-adjusted dose (mg/kg). If well tolerated, doses up to 0.12 mg/kg once daily may provide additional benefit. Doses above 4 mg/day have not been systematically studied in controlled clinical trials.
4. In the adjunctive trial, the majority of subjects reached optimal doses in the 0.05 to
0.12 mg/kg/day range.

In clinical trials, there were dose-related and exposure-related risks for several clinically significant adverse reactions (e.g., hypotension, bradycardia, sedative events). Thus, consideration should be given to dosing an extended-release preparation of guanfacine on a milligram-per-kilogram basis in order to balance the exposure-related potential benefits and risks of treatment.

**YOHIMBINE**

Yohimbine (Yocon) is an $\alpha_2$-adrenergic receptor antagonist that is used as a treatment for both idiopathic and medication-induced erectile disorder. Currently, sildenafil (Viagra) and its congeners and alprostadil (Impulse, Edex) are considered more efficacious for this indication than yohimbine. Yohimbine is derived from an alkaloid found in *Rubaceae* and related trees and in the *Rauwolfia serpentina* plant.

**Pharmacologic Actions**

Yohimbine is erratically absorbed after oral administration, with bioavailability ranging from 7 to 87 percent. There is extensive hepatic first-pass metabolism. Yohimbine affects the sympathomimetic autonomic nervous system by increasing plasma concentrations of norepinephrine. The half-life of yohimbine is 0.5 to 2 hours. Clinically, yohimbine produces increased parasympathetic (cholinergic) tone.

**Therapeutic Indications**

Yohimbine has been used to treat erectile dysfunction. Penile erection has been linked to cholinergic activity and to $\alpha_2$-adrenergic blockade, which theoretically results in increased penile inflow of blood, decreased penile outflow of blood, or both. Yohimbine is reported to help counteract the loss of sexual desire and the orgasmic inhibition caused by some serotonergic antidepressants (e.g., selective serotonin reuptake inhibitors). It has not been found useful in women for these indications.

**Precautions**

The side effects of yohimbine include anxiety, elevated BP and heart rate, increased psychomotor activity, irritability, tremor, headache, skin flushing, dizziness, urinary frequency, nausea, vomiting, and sweating. Patients with panic disorder show heightened sensitivity to yohimbine and experience increased anxiety, increased BP, and increased plasma 3-methoxy-4-hydroxyphenylglycol (MHPG).

Yohimbine should be used with caution in female patients and should not be used in patients with renal disease, cardiac disease, glaucoma, or a history of gastric or duodenal ulcer.

**Drug Interactions**
Yohimbine blocks the effects of clonidine, guanfacine, and other α2-receptor agonists.

**Laboratory Interferences**
No known laboratory interferences are associated with yohimbine use.

**Dosage and Clinical Guidelines**
Yohimbine is available in 5.4-mg tablets. The dosage of yohimbine in the treatment of erectile disorder is approximately 16 mg a day given in doses that range from 2.7 to 5.4 mg three times a day. In the event of significant adverse effects, dose should first be reduced and then gradually increased again. Yohimbine should be used judiciously in psychiatric patients because it may have an adverse effect on their mental status. Because yohimbine has no consistent effect on erectile dysfunction, its use remains controversial. Phosphodiesterase-5 (PDE-5) inhibitors are the preferred medication for this disorder.

**PRAZOSIN**
Prazosin (Minipress) is a quinazoline derivative and one of a new chemical class of antihypertensives. It is an α1-adrenergic receptor antagonist as opposed to the drugs mentioned above, which are α2-blockers.

**Pharmacologic Actions**
The exact mechanism of the hypotensive action of prazosin is unknown, particularly as it effects nightmare suppression. Prazosin causes a decrease in total peripheral resistance that is related to its action as an α1-adrenergic receptor antagonist. BP is lowered in both the supine and standing positions. This effect is most pronounced on the diastolic BP. After oral administration, human plasma concentrations reach a peak at about 3 hours with a plasma half-life of 2 to 3 hours. The drug is highly bound to plasma protein. Tolerance has not been observed to develop with long-term therapy.

**Therapeutic Action**
Prazosin is used in psychiatry to suppress nightmares, particularly those associated with PTSD.

**Precautions and Adverse Reactions**
During clinical trials and subsequent marketing experience, the most frequent reactions were dizziness (10.3 percent); headache (7.8 percent); drowsiness (7.6 percent); lack of energy (6.9 percent); weakness (6.5 percent); palpitations (5.3 percent); and nausea (4.9 percent). In most instances, side effects disappeared with continued therapy or
have been tolerated with no decrease in dose of drug. Prazosin should not be used in nursing mothers or during pregnancy.

**Drug Interactions**
No adverse drug interactions have been reported.

**Laboratory Interferences**
No laboratory interferences have been reported.

**Dosage and Clinical Guidelines**
The drug is supplied in 1-, 2-, and 5-mg capsules and a nasal spray. The therapeutic dosages most commonly used have ranged from 6 to 15 mg daily given in divided doses. Doses higher than 20 mg do not increase efficacy. When adding a diuretic or other antihypertensive agent, the dose should be reduced to 1 or 2 mg three times a day and titration then carried out. Concomitant use with a PDE-5 inhibitor can result in additive BP lowering effects and symptomatic hypotension; therefore, PDE-5 inhibitor therapy should be initiated at the lowest dose in patients taking prazosin.

Table 29.3-2 provides a summary of α₂-adrenergic receptor agonists used in psychiatry.

### 29.4 β-Adrenergic Receptor Antagonists

Because of the innervations of many, if not most, peripheral organs and vasculature by the sympathetic division of the autonomic nervous system, their functions are ultimately controlled, in part, by one of the two major classes of adrenergic receptors: α-receptors (discussed in Section 29.3) and β-receptors. These receptors are further subdivided based on their action and location, and they are located both peripherally and in the central nervous system (CNS). Shortly after being introduced for cardiac indications, propranolol (Inderal) was reported to be useful for agitation, and its use in psychiatry spread rapidly. The five most commonly used β-receptor antagonists in psychiatry are propranolol, nadolol (Corgard), metoprolol (Lopressor, Toprol), pindolol (Visken), and atenolol (Tenormin) (Table 29.4-1).

ISA, intrinsic sympathomimetic activity; OD, once daily; bid, twice a day; tid, three times a day; qid, four times a day.
PHARMACOLOGIC ACTIONS
The β-receptor antagonists differ with regard to lipophilicities, metabolic routes, β-receptor selectivity, and half-lives. The absorption of the β-receptor antagonists from the gastrointestinal tract is variable. The agents that are most soluble in lipids (i.e., are lipophilic) are likely to cross the blood–brain barrier and enter the brain; those agents that are least lipophilic are less likely to enter the brain. When CNS effects are desired, a lipophilic drug may be preferred; when only peripheral effects are desired, a less lipophilic drug may be indicated.

Whereas propranolol, nadolol, pindolol, and labetalol (Normodyne, Trandate) have essentially equal potency at both the β₁- and β₂-receptors, metoprolol and atenolol have greater affinity for the β₁-receptor than for the β₂-receptor. Relative β₁-selectivity confers few pulmonary and vascular effects of these drugs, although they must be used with caution in persons with asthma because the drugs retain some activity at the β₂-receptors.

Pindolol has sympathomimetic effects in addition to its β-antagonist effects, which has allowed its use for augmentation of antidepressant drugs. Pindolol, propranolol, and nadolol possess some antagonist activity at the serotonin 5-HT₁A receptors.

THERAPEUTIC INDICATIONS
Anxiety Disorders
Propranolol is useful for the treatment of social phobia, primarily of the performance type (e.g., disabling anxiety before a musical performance). Data are also available for its use in treatment of panic disorder, posttraumatic stress disorder, and generalized anxiety disorder. In social phobia, the common treatment approach is to take 10 to 40 mg of propranolol 20 to 30 minutes before the anxiety-provoking situation. The β-receptor antagonists are less effective for the treatment of panic disorder than are benzodiazepines or selective serotonin reuptake inhibitors (SSRIs).

Lithium-Induced Postural Tremor
The β-receptor antagonists are beneficial for lithium-induced postural tremor and other medication-induced postural tremors—for example, those induced by tricyclic antidepressants (TCAs) and valproate (Depakene). The initial approach to this movement disorder includes lowering the dose of lithium (Eskalith), eliminating aggravating factors, such as caffeine, and administering lithium at bedtime. If these interventions are inadequate, however, propranolol in the range of 20 to 160 mg a day given two or three times daily is generally effective for the treatment of lithium-induced postural tremor.

Neuroleptic-Induced Acute Akathisia
Many studies have shown that β-receptor antagonists can be effective in the treatment of neuroleptic-induced acute akathisia. They are generally more effective for this indication than are anticholinergics and benzodiazepines. The β-receptor antagonists are not effective in the treatment of such neuroleptic-induced movement disorders as acute dystonia and parkinsonism.

**Aggression and Violent Behavior**

The β-receptor antagonists may be effective in reducing the number of aggressive and violent outbursts in persons with impulse disorders, schizophrenia, and aggression associated with brain injuries such as trauma, tumors, anoxic injury, encephalitis, alcohol dependence, and degenerative disorders (e.g., Huntington’s disease).

**Alcohol Withdrawal**

Propranolol is reported to be useful as an adjuvant to benzodiazepines but not as a sole agent in the treatment of alcohol withdrawal. The following dose schedule is suggested: no propranolol for a pulse rate below 50 beats per minute; 50 mg propranolol for a pulse rate between 50 and 79 beats per minute; and 100 mg propranolol for a pulse rate of 80 beats per minute or above.

**Antidepressant Augmentation**

Pindolol has been used to augment and hasten the antidepressant effects of SSRIs, tricyclic drugs, and electroconvulsive therapy. Small studies have shown that pindolol administered at the onset of antidepressant therapy may shorten the usual 2- to 4-week latency of antidepressant response by several days. Because the β-receptor antagonists may possibly induce depression in some persons, augmentation strategies with these drugs need to be further clarified in controlled trials.

**Other Disorders**

A number of case reports and controlled studies have reported data indicating that β-receptor antagonists may be of modest benefit for persons with schizophrenia and manic symptoms. They have also been used in some cases of stuttering (Table 29.4-2).

| Table 29.4-2 | Psychiatric Uses for β-Adrenergic Receptor Antagonists |
PRECAUTIONS AND ADVERSE REACTIONS

The β-receptor antagonists are contraindicated for use in people with asthma, insulin-dependent diabetes, congestive heart failure, significant vascular disease, persistent angina, and hyperthyroidism. The contraindication in diabetic persons is because of the drugs' antagonizing the normal physiologic response to hypoglycemia. The β-receptor antagonists can worsen atrioventricular (AV) conduction defects and lead to complete AV heart block and death. If the clinician decides that the risk-to-benefit ratio warrants a trial of a β-receptor antagonist in a person with one of these coexisting medical conditions, a β₁-selective agent should be the first choice, and the patient should be monitored. All currently available β-receptor antagonists are excreted in breast milk and should be administered with caution to nursing women.

The most common adverse effects of β-receptor antagonists are hypotension and bradycardia. In persons at risk for these adverse effects, a test dosage of 20 mg a day of propranolol can be given to assess the reaction to the drug. Depression has been associated with lipophilic β-receptor antagonists, such as propranolol, but it is probably rare. Nausea, vomiting, diarrhea, and constipation can also be caused by treatment with these agents. The β-receptor antagonists may blunt cognition in some people. Serious CNS adverse effects (e.g., agitation, confusion, and hallucinations) are rare. Table 29.4-3 lists the possible adverse effects of β-receptor antagonists.

Table 29.4-3
Adverse Effects and Toxicity of β-Adrenergic Receptor Antagonists
DRUG INTERACTIONS
Concomitant administration of propranolol results in increases in plasma concentrations of antipsychotics, anticonvulsants, theophylline (Theo-Dur, Slo-bid), and levothyroxine (Synthroid). Other β-receptor antagonists may have similar effects. The β-receptor antagonists that are eliminated by the kidneys may have similar effects on drugs that are also eliminated by the renal route. Barbiturates, phenytoin (Dilantin), and cigarette smoking increase the elimination of β-receptor antagonists that are metabolized by the liver. Several reports have associated hypertensive crises and bradycardia with the coadministration of β-receptor antagonists and monoamine oxidase inhibitors. Depressed myocardial contractility and AV nodal conduction can occur from concomitant administration of a β-receptor antagonist and calcium channel inhibitors.

LABORATORY INTERFERENCES
The β-receptor antagonists do not interfere with standard laboratory tests.

DOSAGE AND CLINICAL GUIDELINES
Propranolol is available in 10-, 20-, 40-, 60-, 80-, and 90-mg tablets; 4-, 8-, and 80-mg/mL solutions; and 60-, 80-, 120-, and 160-mg sustained-release capsules. Nadolol is available in 20-, 40-, 80-, 120-, and 160-mg tablets. Pindolol is available in 5- and 10-mg
tablets. Metoprolol is available in 50- and 100-mg tablets and 50-, 100-, and 200-mg sustained-release tablets. Atenolol is available in 25-, 50-, and 100-mg tablets. Acebutolol is available in 200- and 400-mg capsules.

For the treatment of chronic disorders, propranolol administration is usually initiated at 10 mg by mouth three times a day or 20 mg by mouth twice daily. The dosage can be raised by 20 to 30 mg a day until a therapeutic effect emerges. The dosage should be leveled off at the appropriate range for the disorder under treatment. The treatment of aggressive behavior sometimes requires dosages up to 80 mg a day, and therapeutic effects may not be seen until the person has been receiving the maximal dosage for 4 to 8 weeks. For the treatment of social phobia, primarily the performance type, the patient should take 10 to 40 mg of propranolol 20 to 30 minutes before the performance.

Pulse and blood pressure (BP) readings should be taken regularly, and the drug should be withheld if the pulse rate is below 50 beats per minute or the systolic BP is below 90 mm Hg. The drug should be temporarily discontinued if it produces severe dizziness, ataxia, or wheezing. Treatment with β-receptor antagonists should never be discontinued abruptly. Propranolol should be tapered by 60 mg a day until a dosage of 60 mg a day is reached, after which the drug should be tapered by 10 to 20 mg a day every 3 or 4 days.

The clinical guidelines for the other drugs listed in this chapter are similar to propranolol, taking into consideration the different doses used. For example, if propranolol is prescribed initially at the lowest available dose (e.g., 10 mg) then metoprolol should be prescribed at its lowest available dose (e.g., 50 mg).

## 29.5 Anticholinergic Agents
Anticholinergic drugs block the actions of atropine. In the clinical practice of psychiatry, the anticholinergic drugs are primarily used to treat medication-induced movement disorders, particularly neuroleptic-induced Parkinsonism, neuroleptic-induced acute dystonia, and medication-induced postural tremor.

**ANTICHOLINERGICS**

**Pharmacologic Actions**

All anticholinergic drugs are well absorbed from the gastrointestinal (GI) tract after oral administration, and all are sufficiently lipophilic to enter the central nervous system (CNS). Trihexyphenidyl (Artane) and benztropine (Cogentin) reach peak plasma concentrations in 2 to 3 hours after oral administration, and their duration of action is 1 to 12 hours. Benztropine is absorbed equally rapidly by intramuscular (IM) and intravenous (IV) administration; IM administration is preferred because of its low risk for adverse effects.

All six anticholinergic drugs listed in this section (Table 29.5-1) block muscarinic acetylcholine receptors, and benztropine has some antihistaminergic effects. None of the available anticholinergic drugs has any effect on the nicotinic acetylcholine receptors. Of these drugs, trihexyphenidyl is the most stimulating agent, perhaps acting through dopaminergic neurons, and benztropine is the least stimulating and thus is least associated with abuse potential.

**IV, intravenous.**

**Therapeutic Indications**

The primary indication for the use of anticholinergics in psychiatric practice is for the treatment of *neuroleptic-induced Parkinsonism*, characterized by tremor, rigidity, cogwheeling, bradykinesia, sialorrhea, stooped posture, and festination. All of the available anticholinergics are equally effective in the treatment of Parkinsonian symptoms. Neuroleptic-induced Parkinsonism is most common in elderly persons and is most frequently seen with high-potency dopamine receptor antagonists (DRAs), for example, haloperidol (Haldol). The onset of symptoms usually occurs after 2 or 3 weeks of treatment. The incidence of neuroleptic-induced Parkinsonism is lower with the
newer antipsychotic drugs of the serotonin–dopamine antagonist (SDA) class.

Another indication for the use of anticholinergics is for the treatment of neuroleptic-induced acute dystonia, which is most common in young men. The syndrome often occurs early in the course of treatment; is commonly associated with high-potency DRAs (e.g., haloperidol); and most commonly affects the muscles of the neck, tongue, face, and back. Anticholinergic drugs are effective both in the short-term treatment of dystonias and in prophylaxis against neuroleptic-induced acute dystonias.

Akathisia is characterized by a subjective and objective sense of restlessness, anxiety, and agitation. Although a trial of anticholinergics for the treatment of neuroleptic-induced acute akathisia is reasonable, these drugs are not generally considered as effective as the β-adrenergic receptor antagonists, the benzodiazepines, and clonidine (Catapres).

Precautions and Adverse Reactions
The adverse effects of the anticholinergic drugs result from blockade of muscarinic acetylcholine receptors. Anticholinergic drugs should be used cautiously, if at all, by persons with prostatic hypertrophy, urinary retention, and narrow-angle glaucoma. The anticholinergics are occasionally used as drugs of abuse because of their mild mood-elevating properties, most notably, trihexyphenidyl.

The most serious adverse effect associated with anticholinergic toxicity is anticholinergic intoxication, which can be characterized by delirium, coma, seizures, agitation, hallucinations, severe hypotension, supraventricular tachycardia, and peripheral manifestations (flushing, mydriasis, dry skin, hyperthermia, and decreased bowel sounds). Treatment should begin with the immediate discontinuation of all anticholinergic drugs. The syndrome of anticholinergic intoxication can be diagnosed and treated with physostigmine (Antilirium, Eserine), an inhibitor of anticholinesterase, 1 to 2 mg IV (1 mg every 2 minutes) or IM every 30 or 60 minutes. Because physostigmine can lead to severe hypotension and bronchial constriction, it should be used only in severe cases and only when emergency cardiac monitoring and life-support services are available.

Drug Interactions
The most common drug–drug interactions with the anticholinergics occur when they are coadministered with psychotropics that also have high anticholinergic activity, such as DRAs, tricyclic and tetracyclic drugs, and monoamine oxidase inhibitors (MAOIs). Many other prescription drugs and over-the-counter cold preparations also induce significant anticholinergic activity. The coadministration of those drugs can result in a life-threatening anticholinergic intoxication syndrome. In addition, anticholinergic drugs can delay gastric emptying, thereby decreasing the absorption of drugs that are broken down in the stomach and usually absorbed in the duodenum (e.g., levodopa [Larodopa] and DRAs).
Laboratory Interferences
No known laboratory interferences have been associated with anticholinergics.

Dosage and Clinical Guidelines
The six anticholinergic drugs discussed in this chapter are available in a range of preparations (see Table 29.5-1).

**Neuroleptic-induced Parkinsonism.** For the treatment of neuroleptic-induced parkinsonism, the equivalent of 1 to 3 mg of benztropine should be given one to two times daily. The anticholinergic drug should be administered for 4 to 8 weeks, and then it should be discontinued to assess whether the person still requires the drug. Anticholinergic drugs should be tapered over a period of 1 to 2 weeks.

Treatment with anticholinergics as prophylaxis against the development of neuroleptic-induced parkinsonism is usually not indicated, because the onset of its symptoms is usually sufficiently mild and gradual to allow the clinician to initiate treatment only after it is clearly indicated. In young men, prophylaxis may be indicated, however, especially if a high-potency DRA is being used. The clinician should attempt to discontinue the antiparkinsonian agent in 4 to 6 weeks to assess whether its continued use is necessary.

**Neuroleptic-induced Acute Dystonia.** For the short-term treatment and prophylaxis of neuroleptic-induced acute dystonia, 1 to 2 mg of benztropine or its equivalent in another drug should be given IM. The dose can be repeated in 20 to 30 minutes, as needed. If the person still does not improve in another 20 to 30 minutes, a benzodiazepine (e.g., 1 mg IM or IV lorazepam [Ativan]) should be given. Laryngeal dystonia is a medical emergency and should be treated with benztropine, up to 4 mg in a 10-minute period, followed by 1 to 2 mg of lorazepam, administered slowly by the IV route.

Prophylaxis against dystonias is indicated in persons who have had one episode or in persons at high risk (young men taking high-potency DRAs). Prophylactic treatment is given for 4 to 8 weeks and then gradually tapered over 1 to 2 weeks to allow assessment of its continued need. The prophylactic use of anticholinergics in persons requiring antipsychotic drugs has largely become a moot issue because of the availability of SDAs, which are relatively free of parkinsonian effects.

**Akathisia.** As mentioned, anticholinergics are not the drugs of choice for this syndrome. The β-adrenergic receptor antagonists and perhaps the benzodiazepines and clonidine are preferable drugs to try initially.

REFERENCES
29.6 Anticonvulsants

The newer anticonvulsants described in this section were developed for the treatment of epilepsy, but were also found to have beneficial effects in psychiatric disorders. In addition, these agents are used as skeletal muscle relaxants and in neurogenic pain. These drugs have a variety of mechanisms including increasing γ-aminobutyric acid (GABA)ergic function or decreasing glutamatergic function. This chapter includes six of the newer anticonvulsants: gabapentin (Neurontin), levetiracetam (Keppra), pregabalin (Lyrica), tiagabine (Gabitril), topiramate (Topamax), and zonisamide (Zonegran), as well as one of the first used anticonvulsants, phenytoin (Dilantin). Carbamazepine (Tegretol), valproate (Depakene, Depakote), lamotrigine (Lamictal), and oxcarbazepine (Trileptal) are discussed in separate sections.

In 2008, the U.S. Food and Drug Administration (FDA) issued a warning that these drugs may increase the risk of suicidal ideation or act in some persons compared with placebo; however, the relative risk for suicidality was higher in patients with epilepsy compared with those with psychiatric disorders. However, some published data contradict the warning by the FDA regarding the use of anticonvulsants and the risk of suicidal thoughts. These studies suggest that anticonvulsants may have a protective effect on suicidal thoughts in bipolar disorder. Considering the inherent increased risk of suicide in persons with bipolar disorder, clinicians should be aware of these warnings.

GABAPENTIN

Gabapentin was first introduced as an antiepileptic drug and was found to have sedative effects that were useful in some psychiatric disorders, especially insomnia. It was also found to be beneficial in reducing neuropathic pain, including postherpetic neuralgia. It is used in anxiety disorders (social phobia and panic disorder), but not as a main intervention in mania or treatment-resistant mood disorders.

Pharmacologic Actions
Gabapentin circulates in the blood largely unbound and is not appreciably metabolized in humans. It is eliminated unchanged by renal excretion and can be removed by hemodialysis. Food only moderately affects the rate and extent of absorption. Clearance is decreased in elderly persons, requiring dosage adjustments. Gabapentin appears to increase cerebral GABA and may inhibit glutamate synthesis as well. It increases human whole blood serotonin concentrations and modulates calcium channels to reduce monoamine release. It has antiseizure as well as antispastic activity and antinociceptive effects in pain.

**Therapeutic Indications**

In neurology, gabapentin is used for the treatment of both general and partial seizures. It is effective in reducing the pain of postherpetic neuralgia and other pain syndromes associated with diabetic neuropathy, neuropathic cancer pain, fibromyalgia, meralgia paresthetica, amputation, and headache. It has been found to be effective in some cases of chronic pruritus.

In psychiatry, gabapentin is used as a hypnotic agent because of its sedating effects. It has anxiolytic properties and benefits patients with social anxiety and panic disorder. It may decrease the craving for alcohol in some patients and improve mood as well; hence, it may have some use in depressed patients. Some bipolar patients have benefited when gabapentin is used adjunctively with mood stabilizers.

**Precautions and Adverse Reactions**

Adverse effects are mild, with the most common being daytime somnolence, ataxia, and fatigue, which are usually dose related. Overdose (over 45 g) has been associated with diplopia, slurred screech, lethargy, and diarrhea, but all patients recovered. The drug is classified as pregnancy category C and is excreted in breast milk, so it is best to avoid it in pregnant women and nursing mothers.

**Drug Interactions**

Gabapentin bioavailability may decrease as much as 20% when administered with antacids. In general, there are no drug interactions. Chronic use does not interfere with lithium administration.

**Laboratory Interferences**

Gabapentin does not interfere with any laboratory tests, although spontaneous reports of false-positive or positive drug toxicology screenings for amphetamines, barbiturates, benzodiazepines, and marijuana have been reported.

**Dosages and Clinical Guidelines**

Gabapentin is well tolerated, and the dosage can be increased to the maintenance range
within a few days. A general approach is to start with 300 mg on day 1, increase to 600 mg on day 2, 900 mg on day 3, and subsequently increase up to 1,800 mg per day in divided doses as needed to relieve symptoms. Final total daily doses tend to be between 1,200 and 2,400 mg per day but occasionally results may be achieved with dosages as low as 200 to 300 mg per day, especially in elderly persons. Sedation is usually the limiting factor in determining the dosage. Some patients have taken dosages as high as 4,800 mg per day.

Gabapentin is available as 100, 300, and 400 mg capsules and as 600 and 800 mg tablets. A 250 mg/5 mL oral solution is also available. Although abrupt discontinuation of gabapentin does not cause withdrawal effects, use of all anticonvulsant drugs should be gradually tapered.

**TOPIRAMATE**

Topiramate (Topamax) was developed as an anticonvulsant and was found useful in a variety of psychiatric and neurologic conditions, including migraine prevention, treatment of obesity, bulimia, binge eating, and alcohol dependence.

**Pharmacologic Actions**

Topiramate has GABAergic effects and increases cerebral GABA in humans. It has 80% oral bioavailability and is not significantly altered by food. It is 15% protein bound, and about 70% of the drug is eliminated by renal excretion. With renal insufficiency topiramate clearance decreases about 50%, so the dosage needs to be decreased. It has a half-life of around 24 hours.

**Therapeutic Indications**

Topiramate is used mainly as an antiepileptic medication and has been found superior to placebo as monotherapy in patients with seizure disorders. It is also used in the prevention of migraine, smoking cessation, pain syndromes (e.g., low back pain), posttraumatic stress disorder (PTSD), and essential tremor. The drug has been associated with weight loss, and that fact has been used to counteract the weight gain caused by many psychotropic drugs. It has also been used in general obesity and in the treatment of bulimia and binge-eating disorder. Self-mutilating behavior may be decreased in borderline personality disorder. It is of little or no benefit in the treatment of psychotic disorders. In one study, the combination of topiramate with bupropion (Wellbutrin) showed some efficacy in bipolar depression, but double-blind, placebo-controlled trials failed to demonstrate topiramate monotherapy efficacy in acute mania in adults.

**Precautions and Adverse Reactions**

The most common adverse effects of topiramate include paresthesias, weight loss, somnolence, anorexia, dizziness, and memory problems. Sometimes disturbances in the sense of taste occur. In many cases, the adverse effects are mild to moderate and can be
attenuated by decreasing the dose. No deaths have been reported during overdose. The drug affects acid–base balance (low serum bicarbonate), which can be associated with cardiac arrhythmias, and the formation of renal calculi in about 1.5% of cases. Patients taking the drug should be encouraged to drink plenty of fluids. It is not known if the drug passes through the placenta or is present in breast milk, and it should be avoided by pregnant women or nursing mothers.

**Drug Interactions**

Topiramate has few drug interactions with other anticonvulsant drugs. Topiramate may increase phenytoin concentrations up to 25% and valproic acid 11%; it does not affect the concentration of carbamazepine, phenobarbital (Luminal), or primidone. Topiramate concentrations are decreased by 40% to 48%, with concomitant administration of carbamazepine or phenytoin. Topiramate should not be combined with other carbonic anhydrase inhibitors, such as acetazolamide (Diamox) or dichlorphenamide (Daranide), because this could increase the risk of nephrolithiasis or heat-related problems (oligohidrosis and hyperthermia).

**Laboratory Interferences**

Topiramate does not interfere with any laboratory tests.

**Dosages and Clinical Guidelines**

Topiramate is available as unscored 25, 100, and 200 mg tablets. To reduce the risk of adverse cognitive and sedative effects, topiramate dosage is titrated gradually over 8 weeks to a maximum of 200 mg twice a day. Off-label topiramate is typically used adjuncitively, starting with 25 mg at bedtime and increasing weekly by 25 mg as necessary and tolerated. Final doses in efforts to promote weight loss are often between 75 and 150 mg per day at bedtime. Doses higher than 400 mg are not associated with increased efficacy. All of the dose can be given at bedtime to take advantage of the sedative effects. Persons with renal insufficiency should reduce doses by half.

**TIAGABINE**

Tiagabine was introduced as a treatment for epilepsy in 1997 and was found to have efficacy in some psychiatric conditions, including acute mania. However, safety concerns (see later) along with a lack of controlled data have limited the use of tiagabine in disorders other than epilepsy.

**Pharmacologic Actions**

Tiagabine is well absorbed with a bioavailability of about 90% and is extensively (96%) bound to plasma proteins. Tiagabine is a cytochrome P450 (CYP)3A substrate and is extensively transformed into inactive 5-oxo-tiagabine and glucuronide metabolites, with
only 2% being excreted unchanged in the urine. The remainder is excreted as metabolites in the feces (65%) and the urine (25%). Tiagabine blocks uptake of the inhibitory amino acid neurotransmitter GABA into neurons and glia, enhancing the inhibitory action of GABA at both GABA\(_A\) and GABA\(_B\) receptors, putatively yielding anticonvulsant and antinociceptive effects, respectively. It has mild blocking effects on histamine 1 (H\(_1\)), serotonin type 1B (5-HT\(_{1B}\)), benzodiazepine, and chloride channel receptors.

**Therapeutic Indications**

Tiagabine is rarely used for psychiatric disorders, and then it is used only for generalized anxiety disorder and insomnia. Its main indication is in generalized epilepsy.

**Precautions and Adverse Reactions**

Tiagabine may cause withdrawal seizures, cognitive or neuropsychiatric problems (impaired concentration, speech or language problems, somnolence, and fatigue), status epilepticus, and sudden unexpected death in epilepsy (SUDEP). Acute oral overdoses of tiagabine have been associated with seizures, status epilepticus, coma, ataxia, confusion, somnolence, drowsiness, impaired speech, agitation, lethargy, myoclonus, stupor, tremors, disorientation, vomiting, hostility, temporary paralysis, and respiratory depression. Deaths have been reported in polydrug overdoses involving tiagabine. Cases of serious rash may occur, including Stevens-Johnson syndrome.

Tiagabine is classified as pregnancy category C because fetal loss and teratogenicity have been demonstrated in animals. It is not known if the drug is excreted in breast milk. Pregnant women and nursing mothers should not be given the drug.

**Laboratory Tests**

Tiagabine does not interfere with any laboratory tests.

**Dosage and Administration**

Tiagabine should not be rapidly loaded or rapidly initiated because of the risk of serious adverse effects. In adults and adolescents 12 years of age or older with epilepsy who are also taking enzyme inducers, tiagabine should be initiated at 4 mg per day and increased weekly by 4 mg per day during the first month. The dose should then be increased weekly by 4 to 8 mg per day for weeks 5 and 6, yielding 24 to 32 mg per day administered in two to four divided doses by week 6. In adults (but not adolescents), tiagabine doses may be further increased weekly by 4 to 8 mg per day to as high as 56 mg per day. Plasma concentrations in patients with epilepsy commonly range between 20 and 100 ng/mL, but do not appear to be systematically related to antiseizure effects and thus are not routinely monitored.
LEVETIRACETAM

Initially developed as a nootropic (memory enhancing) drug, levetiracetam proved to be a potent anticonvulsant and marketed as a treatment for partial seizures. It has been used to treat acute mania and anxiety and to augment antidepressant drug therapy.

Pharmacologic Actions

The central nervous system (CNS) effects are not well understood, but it appears to indirectly enhance GABA inhibition. It is rapidly and completely absorbed, and peak concentrations are reached in 1 hour. Food delays the rate of absorption and decreases the amount of absorption. Levetiracetam is not significantly plasma protein bound and is not metabolized through the hepatic CYP system. Its metabolism involves hydrolysis of the acetamide group. Serum concentrations are not correlated with therapeutic effects.

Therapeutic Indications

The major indication is for the treatment of convulsive disorders, including partial onset seizures, myoclonic seizures, and idiopathic generalized epilepsy. In psychiatry, levetiracetam has been used off label to treat acute mania, as an add-on treatment for major depression, and as an anxiolytic agent.

Precautions and Adverse Reactions

The most common side effects of levetiracetam include drowsiness, dizziness, ataxia, diplopia, memory impairment, apathy, and paresthesias. Some patients develop behavioral disturbances during treatment, and hallucinations may occur. Suicidal patients may become agitated. It should not be used in pregnant or lactating women.

Drug Interactions

There are few if any interactions with other drugs, including other anticonvulsants. There is no interaction with lithium.

Laboratory Interferences

No laboratory interferences have been reported.

Dosages and Clinical Guidelines

The drug is available as 250, 500, 750, and 1,000 mg tablets; 500 mg extended-release tablets; a 100 mg/mL oral solution; and a 100 mg/mL intravenous solution. In epilepsy, the typical adult daily dose is 1,000 mg.

In view of its renal clearance, dosages should be reduced in patients with impaired renal function.
Zonisamide was originally used as an anticonvulsant for the treatment of seizure disorders. It was also found to be useful in bipolar disorder, obesity, and binge-eating disorder.

**Pharmacologic Actions**
Zonisamide blocks sodium channels and may weakly potentiate dopamine and serotonin activity. It also inhibits carbonic anhydrase. Some evidence suggests that it may block calcium channels. Zonisamide is metabolized by the hepatic CYP3A system, so enzyme-inducing agents such as carbamazepine, alcohol, and phenobarbital increase the clearance and reduce the availability of the drug. Zonisamide does not affect the metabolism of other drugs. It has a long half-life of 60 hours, so it is easily dosed once daily, preferably at nighttime.

**Therapeutic Indications**
Its main use is in the treatment of generalized seizure disorders and in refractory partial seizures. In psychiatry, controlled studies found it to be of use in obesity and binge-eating disorder. Uncontrolled trials have found it useful in bipolar disorder, particularly mania; however, further studies are warranted for this indication.

**Precautions and Adverse Reactions**
Zonisamide is a sulfonamide and thus may cause fatal rash and blood dyscrasias, although these events are rare. About 4% of patients develop kidney stones. The most common side effects are drowsiness, cognitive impairment, insomnia, ataxia, nystagmus, paresthesia, speech abnormalities, constipation, diarrhea, nausea, and dry mouth. Weight loss is also a common side effect, which has been exploited as a therapy for patients who have gained weight during treatment with psychotropics or, as mentioned above, have ongoing difficulty controlling their eating. Zonisamide should not be used in pregnant women or breast-feeding mothers.

**Drug Interactions**
Zonisamide does not inhibit CYP isoenzymes and does not instigate drug interactions. It is important not to combine carbonic anhydrase inhibitors with zonisamide because of an increased risk of nephrolithiasis related to increased blood levels of urea.

**Laboratory Interferences**
Zonisamide can elevate hepatic alkaline phosphatase and increase blood urea nitrogen and creatinine.

**Dosages and Clinical Guidelines**
Zonisamide is available in 100 and 200 mg capsules. In epilepsy, the dosage range is 100 to 400 mg per day, with side effects becoming more pronounced at doses above 300 mg. Because of its long half-life, zonisamide can be given once a day.

**PREGABALIN**

Pregabalin is pharmacologically similar to gabapentin. It is believed to work by inhibiting the release of excess excitatory neurotransmitters. It increases neuronal GABA levels, its binding affinity is six times greater than that of gabapentin, and it has a longer half-life.

**Pharmacologic Actions**

Pregabalin exhibits linear pharmacokinetics. It is rapidly absorbed in proportion to its dose. The time to maximal plasma concentration is about 1 hour and that to steady state is within 24 to 48 hours. Pregabalin demonstrates high bioavailability, and it has a mean elimination half-life of about 6.5 hours. Food does not affect absorption. Pregabalin does not bind to plasma proteins and is excreted virtually unchanged (<2% metabolism) by the kidneys. It is not subject to hepatic metabolism and does not induce or inhibit liver enzymes such as the CYP system. Dose reduction may be necessary in patients with creatinine clearance (CLcr) less than 60 mL per minute. Daily doses should be further reduced by approximately 50 percent for each additional 50 percent decrease in CLcr. Pregabalin is highly cleared by hemodialysis, so additional doses may be needed for patients on chronic hemodialysis treatment after each hemodialysis treatment.

**Therapeutic Indications**

Pregabalin is approved for the management of diabetic peripheral neuropathy and postherpetic neuralgia, and for adjunctive treatment of partial onset seizures. It has been found to be of benefit to some patients with generalized anxiety disorder. In studies, no consistent dose–response relationship was found, although 300 mg of pregabalin per day was more effective than 150 mg or 450 mg. Some patients with panic disorder or social anxiety disorder may benefit from pregabalin, but little evidence supports its routine use in treating persons with these disorders. It was most recently approved for the treatment of fibromyalgia.

**Precautions and Adverse Reactions**

The most common adverse events associated with pregabalin use are dizziness, somnolence, blurred vision, peripheral edema, amnesia or loss of memory, and tremors. Pregabalin potentiates sedating effects of alcohol, antihistamines, benzodiazepines, and other CNS depressants. It remains to be seen if pregabalin is associated with benzodiazepine-type withdrawal symptoms. There are scant data about its use in pregnant women or nursing mothers, and it is best avoided in these patients.
Drug Interactions
In view of the absence of hepatic metabolism, pregabalin lacks metabolic drug interactions.

Laboratory Interferences
There are no effects on laboratory tests.

Dosage and Clinical Guidelines
The recommended dose for postherpetic neuralgia is 50 or 100 mg orally three times a day. The recommended dose for diabetic peripheral neuropathy is 100 to 200 mg orally three times a day. Patients with fibromyalgia may require up to 450 to 600 mg per day given in divided doses. Pregabalin is available as 25, 50, 75, 100, 150, 200, 225, and 300 mg capsules.

PHENYTOIN
Phenytoin sodium (Dilantin) is an antiepileptic drug and is related to the barbiturates in chemical structure. It is indicated for the control of generalized tonic–clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures and prevention and treatment of seizures occurring during or after neurosurgery. Studies have shown comparable efficacy of phenytoin to other anticonvulsants in bipolar disorder, but clinicians should take into account the danger of gingival hyperplasia, leukopenia, or anemia and the danger of toxicity caused by nonlinear pharmacokinetics.

Pharmacologic Action
Similar to other anticonvulsants, phenytoin causes blockade of voltage-activated sodium channels and hence is efficacious as an antimanic agent. The plasma half-life after oral administration averages 22 hours, with a range of 7 to 42 hours. Steady-state therapeutic levels are achieved at least 7 to 10 days (5 to 7 half-lives) after initiation of therapy, with recommended doses of 300 mg per day. Serum level should be obtained at least 5 to 7 half-lives after treatment initiation. Phenytoin is excreted in the bile, which is then reabsorbed from the intestinal tract and excreted in the urine. Urinary excretion of phenytoin occurs partly with glomerular filtration and by tubular secretion. Small incremental doses of phenytoin may increase the half-life and produce very substantial increases in serum levels. Patients should adhere strictly to the prescribed dosage, and serial monitoring of phenytoin levels is recommended.

Therapeutic Indications
Apart from its indication in generalized tonic–clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures, phenytoin is also used for the treatment of acute
mania in bipolar disorder.

**Precautions and Adverse Reactions**

The most common adverse reactions reported with phenytoin therapy are usually dose related and include nystagmus, ataxia, slurred speech, decreased coordination, and mental confusion. Other side effects include dizziness, insomnia, transient nervousness, motor twitching, and headaches. There have been rare reports of phenytoin-induced dyskinesias, similar to those induced by phenothiazine and other neuroleptic drugs. More serious side effects include thrombocytopenia, leukopenia, agranulocytosis, and pancytopenia, with or without bone marrow suppression.

A number of reports have suggested the development of lymphadenopathy (local or generalized), including benign lymph node hyperplasia, pseudolymphoma, lymphoma, and Hodgkin’s disease. Prenatal exposure to phenytoin may increase the risks for congenital malformations, and a potentially life-threatening bleeding disorder related to decreased levels of vitamin K–dependent clotting factors may occur in newborns exposed to phenytoin in utero. Hyperglycemia has been reported with phenytoin use; in addition, the agent may increase the serum glucose level in patients with diabetes.

**Drug Interactions**

Acute alcohol intake, amiodarone, chlordiazepoxide, cimetidine, diazepam, disulfiram, estrogens, fluoxetine, H₂-antagonists, isoniazid, methylphenidate, phenothiazines, salicylates, and trazodone may increase phenytoin serum levels. Drugs that may lower phenytoin levels include carbamazepine, chronic alcohol abuse, and reserpine.

**Laboratory Interferences**

Phenytoin may decrease serum concentrations of thyroxine. It may cause increased serum levels of glucose, alkaline phosphatase, and γ-glutamyl transpeptidase.

**Dosage and Clinical Guidelines**

Patients may be started on one 100 mg extended oral capsule three times daily, and the dosage then adjusted to suit individual requirements. Patients may then be switched to once-a-day dosing, which is more convenient. In this case, extended-release capsules may be used. Serial monitoring of phenytoin levels is recommended, and the normal range is usually 10 to 20 μg/mL.

29.7 Antihistamines

Antihistamines are frequently used in the treatment of a variety of psychiatric disorders because of their sedative and anticholinergic activities. Certain antihistamines (antagonists of histamine H$_1$ receptors) are used to treat neuroleptic-induced parkinsonism and neuroleptic-induced acute dystonia and as hypnotics and anxiolytics. Diphenhydramine (Benadryl) is used to treat neuroleptic-induced parkinsonism and neuroleptic-induced acute dystonia and sometimes as a hypnotic. Hydroxyzine hydrochloride (Atarax) and hydroxyzine pamoate (Vistaril) are used as anxiolytics. Promethazine (Phenergan) is used for its sedative and anxiolytic effects.
Cyproheptadine (Periactin) has been used for the treatment of anorexia nervosa and inhibited male and female orgasms caused by serotonergic agents. The antihistamines most commonly used in psychiatry are listed in Table 29.7-1. Second-generation, “nonsedating” H<sub>1</sub> blockers, such as fexofenadine (Allegra), loratadine (Claritin), and cetirizine (Zyrtec) are less commonly used in psychiatric practice. The newer H<sub>2</sub>-receptor antagonists, such as cimetidine, work primarily on gastric mucosa, inhibiting gastric secretion.

### PHARMACOLOGICAL ACTIONS

The H<sub>1</sub> antagonists used in psychiatry are well absorbed from the gastrointestinal (GI) tract. The antiparkinsonian effects of intramuscular (IM) diphenhydramine have their onset in 15 to 30 minutes, and the sedative effects of diphenhydramine peak in 1 to 3 hours. The sedative effects of hydroxyzine and promethazine begin after 20 to 60 minutes and last for 4 to 6 hours. Because all three drugs are metabolized in the liver, persons with hepatic disease, such as cirrhosis, may attain high plasma concentrations with long-term administration. Cyproheptadine is well absorbed after oral administration, and its metabolites are excreted in the urine.

Activation of H<sub>1</sub> receptors stimulates wakefulness; therefore, receptor antagonism causes sedation. All four agents also possess some antimuscarinic cholinergic activity. Cyproheptadine is unique among the drugs because it has both potent antihistamine and serotonin 5-HT<sub>2</sub>-receptor antagonist properties.
THERAPEUTIC INDICATIONS

Antihistamines are useful as a treatment for neuroleptic-induced parkinsonism, neuroleptic-induced acute dystonia, and neuroleptic-induced akathisia. They are an alternative to anticholinergics and amantadine for these purposes. The antihistamines are relatively safe hypnotics, but they are not superior to the benzodiazepines, which have been much better studied in terms of efficacy and safety. The antihistamines have not been proven effective for long-term anxiolytic therapy; therefore, the benzodiazepines, buspirone (BuSpar), or selective serotonin reuptake inhibitors (SSRIs) are preferable for such treatment. Cyproheptadine is sometimes used to treat impaired orgasms, especially delayed orgasm resulting from treatment with serotonergic drugs.

Because it promotes weight gain, cyproheptadine may be of some use in the treatment of eating disorders, such as anorexia nervosa. Cyproheptadine can reduce recurrent nightmares with posttraumatic themes. The antiserotonergic activity of cyproheptadine may counteract the serotonin syndrome caused by concomitant use of multiple serotonin-activating drugs, such as SSRIs and monoamine oxidase inhibitors.

PRECAUTIONS AND ADVERSE REACTIONS

Antihistamines are commonly associated with sedation, dizziness, and hypotension, all of which can be severe in elderly persons, who are also likely to experience the anticholinergic effects of those drugs. Paradoxical excitement and agitation is an adverse effect seen in a small number of persons. Poor motor coordination can result in accidents; therefore, persons should be warned about driving and operating dangerous machinery. Other common adverse effects include epigastric distress, nausea, vomiting, diarrhea, and constipation. Because of mild anticholinergic activity, some people experience dry mouth, urinary retention, blurred vision, and constipation. For this reason also, antihistamines should be used only at very low doses, if at all, by persons with narrow-angle glaucoma or obstructive GI, prostate, or bladder conditions. A central anticholinergic syndrome with psychosis may be induced by either cyproheptadine or diphenhydramine. The use of cyproheptadine in some persons has been associated with weight gain, which may contribute to its reported efficacy in some persons with anorexia nervosa.

In addition to the above adverse effects, antihistamines have some potential for abuse. The coadministration of antihistamines and opioids can increase the euphoria experienced by persons with substance dependence. Overdoses of antihistamines can be fatal. Antihistamines are excreted in breast milk, so their use should be avoided by nursing mothers. Because of some potential for teratogenicity, pregnant women should avoid the use of antihistamines.

DRUG INTERACTIONS

The sedative property of antihistamines can be additive with other central nervous system (CNS) depressants, such as alcohol, other sedative-hypnotic drugs, and many
psychotropic drugs, including tricyclic drugs and dopamine receptor antagonists (DRAs). Anticholinergic activity can also be additive with that of other anticholinergic drugs and may sometimes result in severe anticholinergic symptoms or intoxication.

LABORATORY INTERFERENCES

H₁ antagonists may eliminate the wheal and induration that form the basis of allergy skin tests. Promethazine may interfere with pregnancy tests and may increase blood glucose concentrations. Diphenhydramine may yield a false-positive urine test result for phencyclidine (PCP). Hydroxyzine use can falsely elevate the results of certain tests for urinary 17-hydroxycorticosteroids.

DOSAGE AND CLINICAL GUIDELINES

The antihistamines are available in a variety of preparations (Table 29.7-3). IM injections should be deep, because superficial administration can cause local irritation.

</table>

Intravenous (IV) administration of 25 to 50 mg of diphenhydramine is an effective treatment for neuroleptic-induced acute dystonia, which may immediately disappear. Treatment with 25 mg three times a day—up to 50 mg four times a day, if necessary—can be used to treat neuroleptic-induced parkinsonism, akinesia, and buccal movements. Diphenhydramine can be used as a hypnotic at a 50 mg dose for mild transient insomnia. Doses of 100 mg have not been shown to be superior to doses of 50 mg, but they produce more anticholinergic effects than doses of 50 mg.
Hydroxyzine is most commonly used as a short-term anxiolytic. Hydroxyzine should not be given IV because it is irritating to the blood vessels. Dosages of 50 to 100 mg given orally four times a day for long-term treatment or 50 to 100 mg IM every 4 to 6 hours for short-term treatment are usually effective.

SSRI-induced anorgasmia may sometimes be reversed with 4 to 16 mg a day of cyproheptadine taken by mouth 1 or 2 hours before anticipated sexual activity. A number of case reports and small studies have also reported that cyproheptadine may be of some use in the treatment of eating disorders, such as anorexia nervosa. Cyproheptadine is available in 4 mg tablets and a 2 mg/5 mL solution. Children and elderly patients are more sensitive to the effects of antihistamines than are young adults.

**REFERENCES**

### 29.8 Barbiturates and Similarly Acting Drugs

The first barbiturate to be used in medicine was barbital (Veronal), which was introduced in 1903. It was followed by phenobarbital (Luminal), amobarbital (Amytal), pentobarbital (Nembutal), secobarbital (Seconal), and thiopental (Pentothal). Many others have been synthesized, but only a handful has been used clinically (Table 29.8-1). Many problems are associated with these drugs, including high abuse and addiction.
potential, a narrow therapeutic range with low therapeutic index, and unfavorable side effects. The use of barbiturates and similar compounds such as meprobamate (Miltown) has practically been eliminated by the benzodiazepines and hypnotics, such as zolpidem (Ambien), eszopiclone (Lunesta), and zaleplon (Sonata), which have a lower abuse potential and a higher therapeutic index than the barbiturates. Nevertheless, the barbiturates still have an important role in the treatment of certain mental and convulsive disorders.

IV, intravenous.

### PHARMACOLOGICAL ACTIONS

The barbiturates are well absorbed after oral administration. The binding of barbiturates to plasma proteins is high, but lipid solubility varies. The individual barbiturates are metabolized by the liver and excreted by the kidneys. The half-lives of specific barbiturates range from 1 to 120 hours. The barbiturates may also induce hepatic enzymes (cytochrome P450, CYP), thereby reducing the levels of both the barbiturate and any other concurrently administered drugs metabolized by the liver. The mechanism of action of barbiturates involves the γ-aminobutyric acid (GABA) receptor–benzodiazepine receptor–chloride ion channel complex.

### THERAPEUTIC INDICATIONS

**Electroconvulsive Therapy**

Methohexital (Brevital) is commonly used as an anesthetic agent for electroconvulsive therapy (ECT). It has lower cardiac risks than other barbiturate anesthetics. Used intravenously (IV), methohexital produces rapid unconsciousness, and because of its rapid redistribution, it has a brief duration of action (5 to 7 minutes). Typical dosing for ECT is 0.7 to 1.2 mg/kg. Methohexital can also be used to abort prolonged seizures in
ECT or to limit postictal agitation.

Seizures
Phenobarbital (Solfoton, Luminal), the most commonly used barbiturate for treatment of seizures, has indications for the treatment of generalized tonic-clonic and simple partial seizures. Parenteral barbiturates are used in the emergency management of seizures independent of cause. Intravenous phenobarbital should be administered slowly at 10 to 20 mg/kg for status epilepticus.

Narcoanalysis
Amobarbital (Amytal) has been used historically as a diagnostic aid in a number of clinical conditions, including conversion reactions, catatonia, hysterical stupor, and unexplained muteness, and to differentiate stupor of depression, schizophrenia, and structural brain lesions.

The Amytal interview is performed by placing the patient in a reclining position and administering amobarbital IV at 50 mg a minute. Infusion is continued until lateral nystagmus is sustained or drowsiness is noted, usually at 75 to 150 mg. After this, 25 to 50 mg can be administered every 5 minutes to maintain narcosis. The patient should be allowed to rest for 15 to 30 minutes after the interview before attempting to walk.

Because of the risk of laryngospasm with IV amobarbital, diazepam has become the drug of choice for narcoanalysis.

Sleep
The barbiturates reduce sleep latency and the number of awakenings during sleep, although tolerance to these effects generally develops within 2 weeks. Discontinuation of barbiturates often leads to rebound increases on electroencephalographic measures of sleep and a worsening of the insomnia.
WITHDRAWAL FROM SEDATIVE-HYPNOTICS

Barbiturates are sometimes used to determine the extent of tolerance to barbiturates or other hypnotics to guide detoxification. After intoxication has resolved, a test dose of pentobarbital (200 mg) is given orally. One hour later, the patient is examined. Tolerance and dose requirements are determined by the degree to which the patient is affected. If the patient is not sedated, another 100 mg of pentobarbital can be administered every 2 hours, up to three times (maximum, 500 mg over 6 hours). The amount needed for mild intoxication corresponds to the approximate daily dose of barbiturate used. Phenobarbital (30 mg) may then be substituted for each 100 mg of pentobarbital. This daily dose requirement can be administered in divided doses and gradually tapered by 10 percent a day, with adjustments made according to withdrawal signs.

PRECAUTIONS AND ADVERSE REACTIONS

Some adverse effects of barbiturates are similar to those of benzodiazepines, including paradoxical dysphoria, hyperactivity, and cognitive disorganization. Rare adverse effects associated with barbiturate use include the development of Stevens–Johnson syndrome, megaloblastic anemia, and neutropenia.

Prior to the advent of benzodiazepines, the widespread use of barbiturates as hypnotics and anxiolytics made them the most common cause of acute porphyria reactions. Severe attacks of porphyria have decreased largely because barbiturates are now seldom used and are contraindicated in patients with the disease.

A major difference between the barbiturates and the benzodiazepines is the low therapeutic index of the barbiturates. An overdose of barbiturates can easily prove fatal. In addition to narrow therapeutic indexes, the barbiturates are associated with a significant risk of abuse potential and the development of tolerance and dependence. Barbiturate intoxication is manifested by confusion, drowsiness, irritability, hyporeflexia or areflexia, ataxia, and nystagmus. The symptoms of barbiturate withdrawal are similar to, but more marked than, those of benzodiazepine withdrawal.

Ten times the daily dose or 1 g of most barbiturates causes severe toxicity; 2–10 g generally proves fatal. Manifestations of barbiturate intoxication may include delirium, confusion, excitement, headache, and central nervous system (CNS) and respiratory depression, ranging from somnolence to coma. Other adverse reactions include Cheyne–Stokes respiration, shock, miosis, oliguria, tachycardia, hypotension, hypothermia, irritability, hyporeflexia or areflexia, ataxia, and nystagmus. Treatment of overdose includes induction of emesis or lavage, activated charcoal, and saline cathartics; supportive treatment, including maintaining airway and respiration and treating shock as needed; maintaining vital signs and fluid balance; alkalinizing the urine, which increases excretion; forced diuresis if renal function is normal, or hemodialysis in severe cases.

Because of some evidence of teratogenicity, barbiturates should not be used by
pregnant women or women who are breastfeeding. Barbiturates should be used with caution by patients with a history of substance abuse, depression, diabetes, hepatic impairment, renal disease, severe anemia, pain, hyperthyroidism, or hypoadrenalism. Barbiturates are also contraindicated in patients with acute intermittent porphyria, impaired respiratory drive, or limited respiratory reserve.

**DRUG INTERACTIONS**

The primary area for concern about drug interactions is the potentially dangerous effects of respiratory depression. Barbiturates should be used with great caution with other prescribed CNS drugs (including antipsychotic and antidepressant drugs) and nonprescribed CNS agents (e.g., alcohol). In addition, caution must be exercised when prescribing barbiturates to patients who are taking other drugs that are metabolized in the liver, especially cardiac drugs and anticonvulsants. Because individual patients have a wide range of sensitivities to barbiturate-induced enzyme induction, it is not possible to predict the degree to which the metabolism of concurrently administered medications may be affected. Drugs that have their metabolism enhanced by barbiturate administration include opioids, antiarrhythmic agents, antibiotics, anticoagulants, anticonvulsants, antidepressants, β-adrenergic receptor antagonists, dopamine receptor antagonists, contraceptives, and immunosuppressants.

**LABORATORY INTERFERENCES**

No known laboratory interferences are associated with the administration of barbiturates.

**DOSE AND CLINICAL GUIDELINES**

Barbiturates and other drugs described later begin to act within 1 to 2 hours of administration. The doses of barbiturates vary, and treatment should begin with low doses that are increased to achieve a clinical effect. Children and older people are more sensitive to the effects of the barbiturates than are young adults. The most commonly used barbiturates are available in a variety of dose forms. Barbiturates with half-lives in the 15- to 40-hour range are preferable, because long-acting drugs tend to accumulate in the body. Clinicians should instruct patients clearly about the adverse effects and the potential for dependence associated with barbiturates.

Although determining plasma concentrations of barbiturates is rarely necessary in psychiatry, monitoring of phenobarbital concentrations is standard practice when the drug is used as an anticonvulsant. The therapeutic blood concentrations for phenobarbital in this indication range from 15 to 40 mg/L, although some patients may experience significant adverse effects in that range.

Barbiturates are contained in combination products with which the clinician should be familiar.
OTHER SIMILARLY ACTING DRUGS

A number of agents that act similarly to the barbiturates have been used in the treatment of anxiety and insomnia. Three such available drugs are paraldehyde (Paral), meprobamate, and chloral hydrate (Noctec). These drugs are rarely used because of their abuse potential and potential toxic effects.

**Paraldehyde**

Paraldehyde is a cyclic ether and was first used in 1882 as a hypnotic. It has also been used to treat epilepsy, alcohol withdrawal symptoms, and delirium tremens. Because of its low therapeutic index, it has been supplanted by the benzodiazepines and other anticonvulsants.

**Pharmacologic Actions.** Paraldehyde is rapidly absorbed from the gastrointestinal (GI) tract and from intramuscular (IM) injections. It is primarily metabolized to acetaldehyde by the liver, and unmetabolized drug is expired by the lungs. Reported half-lives range from 3.4 to 9.8 hours. The onset of action is 15 to 30 minutes.

**Therapeutic Indications.** Paraldehyde is not indicated as an anxiolytic or a hypnotic and has little place in current psychopharmacology.

**Precautions and Adverse Reactions.** Paraldehyde frequently causes foul breath because of expired unmetabolized drug. It can inflame pulmonary capillaries and cause coughing. It can also cause local thrombophlebitis with IV use. Patients may experience nausea and vomiting with oral use. Overdose leads to metabolic acidosis and decreased renal output. There is risk of abuse among drug addicts.

**Drug Interactions.** Disulfiram (Antabuse) inhibits acetaldehyde dehydrogenase and reduces metabolism of paraldehyde, leading to possible toxic concentration of paraldehyde. Paraldehyde has addictive sedating effects in combination with other CNS depressants such as alcohol or benzodiazepines.

**Laboratory Interferences.** Paraldehyde can interfere with the metyrapone, phentolamine, and urinary 17-hydroxycorticosteroid tests.

**Dosing and Clinical Guidelines.** Paraldehyde is available in 30-mL vials for oral, IV, or rectal use. For seizures in adults, up to 12 mL (diluted to a 10% solution) can be administered by gastric tube every 4 hours. For children, the oral dose is 0.3 mg/kg.

**Meprobamate**

Meprobamate, a carbamate, was introduced shortly before the benzodiazepines,
specifically to treat anxiety. It is also used for muscle relaxant effects.

**Pharmacologic Actions.** Meprobamate is rapidly absorbed from the GI tract and from IM injections. It is metabolized primarily by the liver, and a small portion is excreted unchanged in urine. The plasma half-life is approximately 10 hours.

**Therapeutic Indications.** Meprobamate is indicated for short-term treatment of anxiety disorders. It has also been used as a hypnotic and is prescribed as a muscle relaxant.

**Precautions and Adverse Reactions.** Meprobamate can cause CNS depression and death in overdose and carries the risk of abuse by patients with drug or alcohol dependence. Abrupt cessation after long-term use can lead to withdrawal syndrome, including seizures and hallucinations. Meprobamate can exacerbate acute intermittent porphyria. Other rare side effects include hypersensitivity reactions, wheezing, hives, paradoxical excitement, and leukopenia. It should not be used in patients with hepatic compromise.

**Drug Interactions.** Meprobamate has additive sedating effects in combination with other CNS depressants, such as alcohol, barbiturates, or benzodiazepines.

**Laboratory Interferences.** Meprobamate can interfere with the metyrapone, phentolamine, and urinary 17-hydroxycorticosteroid tests.

**Dosing and Clinical Guidelines.** Meprobamate is available in 200, 400, and 600 mg tablets; 200 and 400 mg extended-release capsules; and various combinations, for example, aspirin, 325 mg and 200 mg of meprobamate (Equagesic) for oral use. For adults, the usual dose is 400 to 800 mg twice daily. Elderly patients and children aged 6 to 12 years require half the adult dose.

**Chloral Hydrate**

Chloral hydrate is a hypnotic agent rarely used in psychiatry because numerous safer options, such as benzodiazepines, are available.

**Pharmacological Actions.** Chloral hydrate is well absorbed from the GI tract. The parent compound is metabolized within minutes by the liver to the active metabolite trichloroethanol, which has a half-life of 8 to 11 hours. A dose of chloral hydrate induces sleep in about 30 to 60 minutes and maintains sleep for 4 to 8 hours. It probably potentiates GABAergic neurotransmission, which suppresses neuronal excitability.

**Therapeutic Indications.** The major indication for chloral hydrate is to induce
sleep. It should be used for no more than 2 or 3 days because longer-term treatment is associated with an increased incidence and severity of adverse effects. Tolerance develops to the hypnotic effects of chloral hydrate after 2 weeks of treatment. The benzodiazepines are superior to chloral hydrate for all psychiatric uses.

**Precautions and Adverse Reactions.** Chloral hydrate has adverse effects on the CNS, GI system, and skin. High doses (>4 g) may be associated with stupor, confusion, ataxia, falls, or coma. The GI effects include nonspecific irritation, nausea, vomiting, flatulence, and an unpleasant taste. With long-term use and overdose, gastritis and gastric ulceration can develop. In addition to the development of tolerance, dependence on chloral hydrate can occur, with symptoms similar to those of alcohol dependence. With a lethal dose between 5,000 and 10,000 mg, chloral hydrate is a particularly poor choice for potentially suicidal persons.

**Drug Interactions.** Because of metabolic interference, chloral hydrate should be strictly avoided with alcohol, a notorious concoction known as a *Mickey Finn*. Chloral hydrate may displace warfarin (Coumadin) from plasma proteins and enhance anticoagulant activity; this combination should be avoided.

**Laboratory Interferences.** Chloral hydrate administration can lead to false-positive results for urine glucose determinations that use cupric sulfate (e.g., Clinitest) but not in tests that use glucose oxidase (e.g., Clinistix and Tes-Tape). Chloral hydrate can also interfere with the determination of urinary catecholamines in 17-hydroxycorticosteroids.

**Dosing and Clinical Guidelines.** Chloral hydrate is available in 500 mg capsules; 500 mg/5 mL solution; and 324, 500, and 648 mg rectal suppositories. The standard dose of chloral hydrate is 500 to 2,000 mg at bedtime. Because the drug is a GI irritant, it should be administered with excess water, milk, other liquids, or antacids to decrease gastric irritation.

**Propofol**

Propofol (Diprivan) is a GABA_\text{A} agonist that is used as an anesthetic. It induces presynaptic release of GABA and dopamine (the latter possibility through an action on GABA_\text{B} receptors) and is a partial agonist at dopamine D_2 and N-methyl-\text{D}-aspartate (NMDA) receptors. Because it is very lipid soluble, it crosses the blood–brain barrier readily and induces anesthesia in less than 1 minute. Rapid redistribution from the CNS results in offset of action within 3 to 8 minutes after the infusion is discontinued. It is well tolerated when used for conscious sedation, but it has a potential for acute adverse effects, including respiratory depression, apnea, and bradyarrhythmias, and prolonged infusion can cause acidosis and mitochondrial myopathies. The carrier used for the infusion is a soybean emulsion that can be a culture medium for various organisms. In
addition, the carrier can impair macrophage function and cause hematologic and lipid abnormalities and anaphylactic reactions.

**Etomidate**

Etomidate is a carboxylated imidazole that acts at the $\beta_2$ and $\beta_3$ subunits of the GABA$_A$ receptor. It has a rapid onset (1 minute) and short duration (less than 5 minutes) of action. The propylene glycol vehicle has been linked to hyperosmolar metabolic acidosis. It has both proconvulsant and anticonvulsant properties, and it inhibits cortisol release, with possible adverse consequences after long-term use.

**REFERENCES**

### 29.9 Benzodiazepines and Drugs Acting on GABA Receptors

The first benzodiazepine to be introduced was chlordiazepoxide (Librium), in 1959. In 1963, diazepam (Valium) became available. Over the next three decades, superior safety and tolerability helped the benzodiazepines replace the older antianxiety and hypnotic medications, such as the barbiturates and meprobamate (Miltown). Dozens of benzodiazepines and drugs acting on benzodiazepine receptors have been synthesized and marketed worldwide. Many of these agents are not in the United States, and some benzodiazepines have been discontinued because of lack of use. **Table 29.9-1** lists agents currently available in the United States.
The benzodiazepines derive their name from their molecular structure. They share a common effect on receptors that have been termed benzodiazepine receptors, which in turn modulate γ-aminobutyric acid (GABA) activity. Nonbenzodiazepine agonists, such as zolpidem (Ambien), zaleplon (Sonata), and eszopiclone (Lunesta)—the so-called “Z drugs”—are discussed in this chapter because their clinical effects result from binding domains located close to benzodiazepine receptors. Flumazenil (Romazicon), a benzodiazepine receptor antagonist used to reverse benzodiazepine-induced sedation and in emergency care of benzodiazepine overdosage, is also covered here.

Because benzodiazepines have a rapid anxiolytic sedative effect, they are most commonly used for acute treatment of insomnia, anxiety, agitation, or anxiety associated with any psychiatric disorder. In addition, the benzodiazepines are used as anesthetics, anticonvulsants, and muscle relaxants and as the preferred treatment for catatonia. Because of the risk of psychological and physical dependence associated with long-term use of benzodiazepines, ongoing assessment should be made as to the continued clinical need for these drugs in treating patients. In most patients, given the nature of their disorders, it is often best if benzodiazepine agents are used in conjunction with psychotherapy and when alternative agents have been tried and proven ineffective or poorly tolerated. In many forms of chronic anxiety disorders, antidepressant drugs such as the selective serotonin reuptake inhibitor (SSRI) and serotonin–norepinephrine reuptake inhibitors (SNRIs) are now used as primary...
treatments, with benzodiazepines used as adjuncts. Benzodiazepine abuse is rare, usually found in patients who abuse multiple prescription and recreational drugs.

**PHARMACOLOGIC ACTIONS**

All benzodiazepines except clorazepate (Tranxene) are completely absorbed after oral administration and reach peak serum levels within 30 minutes to 2 hours. Metabolism of clorazepate in the stomach converts it to desmethyldiazepam, which is then completely absorbed.

The absorption, the attainment of peak concentrations, and the onset of action are quickest for diazepam (Valium), lorazepam (Ativan), alprazolam (Xanax), triazolam (Halcion), and estazolam (ProSom). The rapid onset of effects is important to persons who take a single dose of a benzodiazepine to calm an episodic burst of anxiety or to fall asleep rapidly. Several benzodiazepines are effective after intravenous (IV) injection, but only lorazepam and midazolam (Versed) have rapid and reliable absorption after intramuscular (IM) administration.

Diazepam, chlordiazepoxide, clonazepam (Klonopin), clorazepate, flurazepam (Dalmane), and quazepam (Doral) have plasma half-lives of 30 hours to more than 100 hours and are technically described as long-acting benzodiazepines. The plasma half-lives of these compounds can be as high as 200 hours in persons whose metabolism is genetically slow. Because the attainment of steady-state plasma concentrations of the drugs can take up to 2 weeks, persons may experience symptoms and signs of toxicity after only 7 to 10 days of treatment with a dosage that seemed initially to be in the therapeutic range.

Clinically, half-life alone does not necessarily determine the duration of therapeutic action for most benzodiazepines. The fact that all benzodiazepines are lipid soluble to varying degrees means that benzodiazepines and their active metabolites bind to plasma proteins. The extent of this binding is proportional to their lipid solubility. The amount of protein binding varies from 70 to 99 percent. Distribution, onset, and termination of action after a single dose are thus largely determined by benzodiazepine lipid solubility, not elimination half-life. Preparations with high lipid solubility, such as diazepam and alprazolam, are absorbed rapidly from the GI tract and distribute rapidly to the brain by passive diffusion along a concentration gradient, resulting in a rapid onset of action. However, as the concentration of the medication increases in the brain and decreases in the bloodstream, the concentration gradient reverses itself, and these medications leave the brain rapidly, resulting in fast cessation of drug effect. Drugs with longer elimination half-lives, such as diazepam, may remain in the bloodstream for a substantially longer period of time than their actual pharmacologic action at benzodiazepine receptors because the concentration in the brain decreases rapidly below the level necessary for a noticeable effect. In contrast, lorazepam, which has a shorter elimination half-life than diazepam but is less lipid soluble, has a slower onset of action after a single dose because the drug is absorbed and enters the brain more slowly. However, the duration of action after a single dose is longer because it takes longer for
lorazepam to leave the brain and for brain levels to decrease below the concentration that produces an effect. In chronic dosing, some of these differences are not as apparent because brain levels are in equilibrium with higher and more consistent steady-state blood levels, but additional doses still produce a more rapid but briefer action with diazepam than with lorazepam. Benzodiazepines are distributed widely in adipose tissue. As a result, medications may persist in the body after discontinuation longer than would be predicted from their elimination half-lives. In addition, the dynamic half-life (i.e., duration of action on the receptor) may be longer than the elimination half-life.

The advantages of long–half-life drugs over short–half-life drugs include less frequent dosing, less variation in plasma concentration, and less severe withdrawal phenomena. The disadvantages include drug accumulation, increased risk of daytime psychomotor impairment, and increased daytime sedation.

The half-lives of lorazepam, oxazepam (Serax), temazepam (Restoril), and estazolam are between 8 and 30 hours. Alprazolam has a half-life of 10 to 15 hours, and triazolam has the shortest half-life (2 to 3 hours) of all the orally administered benzodiazepines. Rebound insomnia and anterograde amnesia are thought to be more of a problem with the short–half-life drugs than with the long–half-life drugs.

Because administration of medications more frequently than the elimination half-life leads to drug accumulation, medications such as diazepam and flurazepam accumulate with daily dosing, eventually resulting in increased daytime sedation.

Some benzodiazepines (e.g., oxazepam) are conjugated directly by glucuronidation and are excreted. Most benzodiazepines are oxidized first by CYP3A4 and CYP2C19, often to active metabolites. These metabolites may then be hydroxylated to another active metabolite. For example, diazepam is oxidized to desmethyldiazepam, which, in turn, is hydroxylated to produce oxazepam. These products undergo glucuronidation to inactive metabolites. A number of benzodiazepines (e.g., diazepam, chlordiazepoxide) have the same active metabolite (desmethyldiazepam), which has an elimination half-life of more than 120 hours. Flurazepam (Dalmane), a lipid-soluble benzodiazepine used as a hypnotic that has a short elimination half-life, has an active metabolite (desalkylflurazepam) with a half-life greater than 100 hours. This is another reason that the duration of action of a benzodiazepine may not correspond to the half-life of the parent drug.

Zaleplon, zolpidem, and eszopiclone are structurally distinct and vary in their binding to the GABA receptor subunits. Benzodiazepines activate all three specific GABA–benzodiazepine (GABA–BZ) binding sites of the GABA_A receptor, which opens chloride channels and reduces the rate of neuronal and muscle firing. Zolpidem, zaleplon, and eszopiclone have selectivity for certain subunits of the GABA receptor. This may account for their selective sedative effects and relative lack of muscle relaxant and anticonvulsant effects.

Zolpidem, zaleplon, and eszopiclone are rapidly and well absorbed after oral administration, although absorption can be delayed by as long as 1 hour if they are taken with food. Zolpidem reaches peak plasma concentrations in 1.6 hours and has a
half-life of 2.6 hours. Zaleplon reaches peak plasma concentrations in 1 hour and has a half-life of 1 hour. If taken immediately after a high-fat or heavy meal, the peak is delayed by approximately 1 hour, reducing the effects of eszopiclone on sleep onset. The terminal-phase elimination half-life is approximately 6 hours in healthy adults. Eszopiclone is weakly bound to plasma protein (52 to 59 percent).

The rapid metabolism and lack of active metabolites of zolpidem, zaleplon, and eszopiclone avoid the accumulation of plasma concentrations compared with the long-term use of benzodiazepines.

THERAPEUTIC INDICATIONS

Insomnia

Because insomnia may be a symptom of a physical or psychiatric disorder, hypnotics should not be used for more than 7 to 10 consecutive days without a thorough investigation of the cause of the insomnia. However, many patients have long-standing sleep difficulties and benefit greatly from long-term use of hypnotic agents. Temazepam, flurazepam, and triazolam are benzodiazepines with a sole indication for insomnia. Zolpidem, zaleplon, and eszopiclone are also indicated only for insomnia. Although these “Z drugs” are not usually associated with rebound insomnia after the discontinuation of their use for short periods, some patients experience increased sleep difficulties the first few nights after discontinuing their use. Use of zolpidem, zaleplon, and eszopiclone for periods longer than 1 month is not associated with the delayed emergence of adverse effects. No development of tolerance to any parameter of sleep measurement was observed over 6 months in clinical trials of eszopiclone.

Flurazepam, temazepam, quazepam, estazolam, and triazolam are the benzodiazepines approved for use as hypnotics. The benzodiazepine hypnotics differ principally in their half-lives; flurazepam has the longest half-life, and triazolam has the shortest. Flurazepam may be associated with minor cognitive impairment on the day after its administration, and triazolam may be associated with mild rebound anxiety and anterograde amnesia. Quazepam may be associated with daytime impairment when used for a long time. Temazepam or estazolam may be a reasonable compromise for most adults. Estazolam produces rapid onset of sleep and a hypnotic effect for 6 to 8 hours.

γ-Hydroxybutyrate (GHB, Xyrem), which is approved for the treatment of narcolepsy and improves slow-wave sleep, is also an agonist at the GABA_A receptor, where it binds to specific GHB receptors. GHB has the capacity both to reduce drug craving and to induce dependence, abuse, and absence seizures as a result of complex actions on tegmental dopaminergic systems.

Anxiety Disorders

Generalized Anxiety Disorder. Benzodiazepines are highly effective for the relief of anxiety associated with generalized anxiety disorder (GAD). Most persons
should be treated for a predetermined, specific, and relatively brief period. However, because GAD is a chronic disorder with a high rate of recurrence, some persons with GAD may warrant long-term maintenance treatment with benzodiazepines.

**Panic Disorder.** Alprazolam and clonazepam, both high-potency benzodiazepines, are commonly used medications for panic disorder with or without agoraphobia. Although the SSRIs are also indicated for treatment of panic disorder, the benzodiazepines have the advantage of working quickly and not causing significant sexual dysfunction and weight gain. However, the SSRIs are still often preferred because they target common comorbid conditions, such as depression or obsessive-compulsive disorder (OCD). Benzodiazepines and SSRIs can be initiated together to treat acute panic symptoms; use of the benzodiazepine can be tapered after 3 to 4 weeks after the therapeutic benefits of the SSRI have emerged.

**Social Phobia.** Clonazepam has been shown to be an effective treatment for social phobia. In addition, several other benzodiazepines (e.g., diazepam) have been used as adjunctive medications for treatment of social phobia.

**Other Anxiety Disorders.** Benzodiazepines are used adjunctively for treatment of adjustment disorder with anxiety, pathological anxiety associated with life events (e.g., after an accident), OCD, and posttraumatic stress disorder.

**Anxiety Associated with Depression.** Depressed patients often experience significant anxiety, and antidepressant drugs may cause initial exacerbation of these symptoms. Accordingly, benzodiazepines are indicated for the treatment of anxiety associated with depression.

**Bipolar I and II Disorders**
Clonazepam, lorazepam, and alprazolam are effective in the management of acute manic episodes and as an adjuvant to maintenance therapy in lieu of antipsychotics. As an adjuvant to lithium (Eskalith) or lamotrigine (Lamictal), clonazepam may result in an increased time between cycles and fewer depressive episodes. Benzodiazepines may help patients with bipolar disorder sleep better.

**Catatonia**
Lorazepam, sometimes in low doses (less than 5 mg per day) and sometimes in very high doses (12 mg per day or more), is regularly used to treat acute catatonia, which is more frequently associated with bipolar disorder than with schizophrenia. Other benzodiazepines have also been said to be helpful. However, there are no valid controlled trials of benzodiazepines in catatonia. Chronic catatonia does not respond as well to benzodiazepines. The definitive treatment for catatonia is electroconvulsive therapy.
Akathisia
The first-line drug for akathisia is most commonly a β-adrenergic receptor antagonist. However, benzodiazepines are also effective in treating some patients with akathisia.

Parkinson’s Disease
A small number of persons with idiopathic Parkinson’s disease respond to long-term use of zolpidem with reduced bradykinesia and rigidity. Zolpidem dosages of 10 mg four times daily may be tolerated without sedation for several years.

Other Psychiatric Indications
Chlordiazepoxide (Librium) and clorazepate (Tranxene) are used to manage the symptoms of alcohol withdrawal. The benzodiazepines (especially IM lorazepam) are used to manage substance induced and psychotic agitation in the emergency department. Benzodiazepines have been used instead of amobarbital (Amytal) for drug-assisted interviewing.

Flumazenil for Benzodiazepine Overdosage
Flumazenil is used to reverse the adverse psychomotor, amnestic, and sedative effects of benzodiazepine receptor agonists, including benzodiazepines, zolpidem, and zaleplon. Flumazenil is administered IV and has a half-life of 7 to 15 minutes. The most common adverse effects of flumazenil are nausea, vomiting, dizziness, agitation, emotional lability, cutaneous vasodilation, injection-site pain, fatigue, impaired vision, and headache. The most common serious adverse effect associated with the use of flumazenil is the precipitation of seizures, which is especially likely to occur in persons with seizure disorders, those who are physically dependent on benzodiazepines, and those who have ingested large quantities of benzodiazepines. Flumazenil alone may impair memory retrieval.

In mixed-drug overdosage, the toxic effects (e.g., seizures and cardiac arrhythmias) of other drugs (e.g., tricyclic antidepressants) may emerge with the reversal of the benzodiazepine effects of flumazenil. For example, seizures caused by an overdosage of tricyclic antidepressants may have been partially treated in a person who had also taken an overdosage of benzodiazepines. With flumazenil treatment, the tricyclic-induced seizures or cardiac arrhythmias may appear and result in a fatal outcome. Flumazenil does not reverse the effects of ethanol, barbiturates, or opioids.

For the initial management of a known or suspected benzodiazepine overdosage, the recommended initial dosage of flumazenil is 0.2 mg (2 mL) administered IV over 30 seconds. If the desired consciousness is not obtained after 30 seconds, a further dose of 0.3 mg (3 mL) can be administered over 30 seconds. Further doses of 0.5 mg (5 mL) can be administered over 30 seconds at 1-minute intervals up to a cumulative dose of 3.0 mg. The clinician should not rush the administration of flumazenil. A secure airway and
IV access should be established before the administration of the drug. Persons should be awakened gradually.

Most persons with a benzodiazepine overdose response to a cumulative dose of 1 to 3 mg of flumazenil; doses above 3 mg of flumazenil do not reliably produce additional effects. If a person has not responded 5 minutes after receiving a cumulative dose of 5 mg of flumazenil, the major cause of sedation is probably not benzodiazepine receptor agonists, and additional flumazenil is unlikely to have an effect.

Sedation can return in 1 to 3 percent of persons treated with flumazenil. It can be prevented or treated by giving repeated dosages of flumazenil at 20-minute intervals. For repeat treatment, no more than 1 mg (given as 0.5 mg a minute) should be given at any one time, and no more than 3 mg should be given in any 1 hour.

**PRECAUTIONS AND ADVERSE REACTIONS**

The most common adverse effect of the benzodiazepines is drowsiness, which occurs in about 10 percent of all persons. Because of this adverse effect, persons should be advised to be careful while driving or using dangerous machinery when taking the drugs. Drowsiness can be present during the day after the use of a benzodiazepine for insomnia the previous night, the so-called residual daytime sedation. Some persons also experience ataxia (fewer than 2 percent) and dizziness (less than 1 percent). These symptoms can result in falls and hip fractures, especially in elderly persons. The most serious adverse effects of the benzodiazepines occur when other sedative substances, such as alcohol, are taken concurrently. These combinations can result in marked drowsiness, disinhibition, or even respiratory depression. Infrequently, benzodiazepine receptor agonists cause mild cognitive deficits that may impair job performance. Persons taking benzodiazepine receptor agonists should be advised to exercise additional caution when driving or operating dangerous machinery.

High-potency benzodiazepines, especially triazolam, can cause anterograde amnesia. A paradoxical increase in aggression has been reported in persons with preexisting brain damage. Allergic reactions to the drugs are rare, but a few studies report maculopapular rashes and generalized itching. The symptoms of benzodiazepine intoxication include confusion, slurred speech, ataxia, drowsiness, dyspnea, and hyporeflexia.

Triazolam has received significant attention in the media because of an alleged association with serious aggressive behavioral manifestations. Therefore, the manufacturer recommends that the drug be used for no more than 10 days for treatment of insomnia and that physicians carefully evaluate the emergence of any abnormal thinking or behavioral changes in persons treated with triazolam, giving appropriate consideration to all potential causes. Triazolam was banned in Great Britain in 1991.

Zolpidem (Ambien) has also been associated with automatic behavior and amnesia. Persons with hepatic disease and elderly persons are particularly likely to have adverse effects and toxicity from the benzodiazepines, including hepatic coma, especially when the drugs are administered repeatedly or in high dosages.
Benzodiazepines can produce clinically significant impairment of respiration in persons with chronic obstructive pulmonary disease and sleep apnea. Alprazolam may exert a direct appetite stimulant effect and may cause weight gain. The benzodiazepines should be used with caution by persons with a history of substance abuse, cognitive disorders, renal disease, hepatic disease, porphyria, central nervous system (CNS) depression, or myasthenia gravis.

Some data indicate that benzodiazepines are teratogenic; therefore, their use during pregnancy is not advised. Moreover, the use of benzodiazepines in the third trimester can precipitate a withdrawal syndrome in newborns. The drugs are secreted in the breast milk in sufficient concentrations to affect newborns. Benzodiazepines may cause dyspnea, bradycardia, and drowsiness in nursing babies.

Zolpidem and zaleplon are generally well tolerated. At zolpidem dosages of 10 mg per day and zaleplon dosages above 10 mg per day, a small number of persons will experience dizziness, drowsiness, dyspepsia, or diarrhea. Zolpidem and zaleplon are secreted in breast milk and are therefore contraindicated for use by nursing mothers. The dosage of zolpidem and zaleplon should be reduced in elderly persons and persons with hepatic impairment.

In rare cases, zolpidem may cause hallucinations and behavioral changes. The coadministration of zolpidem and SSRIs may extend the duration of hallucinations in susceptible patients.

Eszopiclone exhibits a dose–response relationship in elderly adults for the side effects of pain, dry mouth, and unpleasant taste.

Tolerance, Dependence, and Withdrawal

When benzodiazepines are used for short periods (1 to 2 weeks) in moderate dosages, they usually cause no significant tolerance, dependence, or withdrawal effects. The short-acting benzodiazepines (e.g., triazolam) may be an exception to this rule because some persons have reported increased anxiety the day after taking a single dose of the drug and then stopping its use. Some persons also report a tolerance for the anxiolytic effects of benzodiazepines and require increased doses to maintain the clinical remission of symptoms.

The appearance of a withdrawal syndrome, also called a discontinuation syndrome, depends on the length of time the person has been taking a benzodiazepine, the dosage the person has been taking, the rate at which the drug is tapered, and the half-life of the compound. Benzodiazepine withdrawal syndrome consists of anxiety, nervousness, diaphoresis, restlessness, irritability, fatigue, lightheadedness, tremor, insomnia, and weakness (Table 29.9-2). Abrupt discontinuation of benzodiazepines, particularly those with short half-lives, is associated with severe withdrawal symptoms, which may include depression, paranoia, delirium, and seizures. These severe symptoms are more likely to occur if flumazenil is used for rapid reversal of the benzodiazepine receptor agonist effects. Some features of the syndrome may occur in as many as 90 percent of persons treated with the drugs. The development of a severe withdrawal syndrome is seen only
in persons who have taken high dosages for long periods. The appearance of the syndrome may be delayed for 1 or 2 weeks in persons who had been taking benzodiazepines with long half-lives. Alprazolam seems to be particularly associated with an immediate and severe withdrawal syndrome and should be tapered gradually.

When the medication is to be discontinued, the drug must be tapered slowly (25 percent a week); otherwise, recurrence or rebound of symptoms is likely. Monitoring of any withdrawal symptoms (possibly with a standardized rating scale) and psychological support of the person are helpful in the successful accomplishment of benzodiazepine discontinuation. Concurrent use of carbamazepine (Tegretol) during benzodiazepine discontinuation has been reported to permit a more rapid and better tolerated withdrawal than does a gradual taper alone. The dosage range of carbamazepine used to facilitate withdrawal is 400 to 500 mg a day. Some clinicians report particular difficulty in tapering and discontinuing alprazolam, especially in persons who have been receiving high dosages for long periods. There have been reports of successful discontinuation of alprazolam by switching to clonazepam, which is then gradually withdrawn.

Zolpidem and zaleplon can produce a mild withdrawal syndrome lasting 1 day after prolonged use at higher therapeutic dosages. Rarely, a person taking zolpidem has self-titrated up the daily dosage to 30 to 40 mg a day. Abrupt discontinuation of such a high dosage of zolpidem may cause withdrawal symptoms for 4 or more days. Tolerance does not develop to the sedative effects of zolpidem and zaleplon.

**DRUG INTERACTIONS**

The most common and potentially serious benzodiazepine receptor agonist interaction is excessive sedation and respiratory depression occurring when benzodiazepines, zolpidem, or zaleplon are administered concomitantly with other CNS depressants, such as alcohol, barbiturates, tricyclic and tetracyclic drugs, dopamine receptor antagonists, opioids, and antihistamines. Ataxia and dysarthria may be likely to occur when lithium, antipsychotics, and clonazepam are combined. The combination of benzodiazepines and clozapine (Clozaril) has been reported to cause delirium and should be avoided. Cimetidine (Tagamet), disulfiram (Antabuse), isoniazid, estrogen, and oral contraceptives increase the plasma concentration of diazepam, chlordiazepoxide, clorazepate, and flurazepam. Cimetidine increases the plasma concentrations of zaleplon. However, antacids may reduce the GI absorption of benzodiazepines. The
plasma concentrations of triazolam and alprazolam are increased to potentially toxic concentrations by nefazodone (Serzone) and fluvoxamine (Luvox). The manufacturer of nefazodone recommends that the dosage of triazolam be lowered by 75 percent and the dosage of alprazolam be lowered by 50 percent when given concomitantly with nefazodone. Over-the-counter preparations of kava plant, advertised as a “natural tranquilizer,” can potentiate the action of benzodiazepine receptor agonists through synergistic overactivation of GABA receptors. Carbamazepine can lower the plasma concentration of alprazolam. Antacids and food may decrease the plasma concentrations of benzodiazepines, and smoking may increase the metabolism of benzodiazepines. Rifampin (Rifadin), phenytoin (Dilantin), carbamazepine, and phenobarbital (Solfoton, Luminal) significantly increase the metabolism of zaleplon. The benzodiazepines may increase the plasma concentrations of phenytoin and digoxin (Lanoxin). The SSRIs may prolong and exacerbate the severity of zolpidem-induced hallucinations. Deaths have been reported when parental lorazepam is given with parental olanzapine.

The CYP3A4 and CYP2E1 enzymes are involved in the metabolism of eszopiclone. Eszopiclone did not show any inhibitory potential on CYP450 1A2, 2A6, 2C9, 2C19, 2D6, 2E1, and 3A4 in cryopreserved human hepatocytes. Coadministration of 3 mg of eszopiclone to subjects receiving 400 mg of ketoconazole, a potent inhibitor of CYP3A4, resulted in a 2.2-fold increase in exposure to eszopiclone.

LABORATORY INTERFERENCES

No known laboratory interferences are associated with the use of the benzodiazepines, zolpidem, and zaleplon.

DOSAGE AND CLINICAL GUIDELINES

The clinical decision to treat an anxious person with a benzodiazepine should be carefully considered. Medical causes of anxiety (e.g., thyroid dysfunction, caffeinism, and prescription medications) should be ruled out. Benzodiazepine use should be started at a low dosage, and the person should be instructed regarding the drug’s sedative properties and abuse potential. An estimated length of therapy should be decided at the beginning of therapy, and the need for continued therapy should be reevaluated at least monthly because of the problems associated with long-term use. However, certain persons with anxiety disorders are unresponsive to treatments other than benzodiazepines in long-term use.

Benzodiazepines are available in a wide range of formulations. Clonazepam is available in a wafer formulation that facilitates its use in patients who have trouble swallowing pills. Alprazolam is available in an extended-release form, which reduces the frequency of dosing. Some benzodiazepines are more potent than others in that one compound requires a relatively smaller dosage than another compound to achieve the same effect. For example, clonazepam requires 0.25 mg to achieve the same effect as 5 mg of diazepam; thus, clonazepam is considered a high-potency benzodiazepine.
Conversely, oxazepam has an approximate dosage equivalence of 15 mg and is a low-potency drug.

Zaleplon is available in 5- and 10-mg capsules. A single 10-mg dose is the usual adult dose. The dose can be increased to a maximum of 20 mg as tolerated. A single dose of zaleplon can be expected to provide 4 hours of sleep with minimal residual impairment. For persons older than age 65 years or persons with hepatic impairment, an initial dose of 5 mg is advised.

Eszopiclone is available in 1-, 2-, and 3-mg tablets. The starting dose should not exceed 1 mg in patients with severe hepatic impairment or those taking potent CYP3A4 inhibitors. The recommended dosing to improve sleep onset or maintenance is 2 or 3 mg for adult patients (ages 18 to 64 years) and 2 mg for older adult patients (ages 65 years and older). The 1-mg dose is for sleep onset in older adult patients whose primary complaint is difficulty falling asleep.

Table 29.9-1 lists preparations and doses of medications discussed in this chapter.

REFERENCES

## 29.10 Bupropion

Bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL, Zyban) is an antidepressant drug that inhibits the reuptake of norepinephrine and, possibly, dopamine. Most significantly, it does not act on the serotonin system like SSRI antidepressants. This results in a side effect profile characterized by a low risk of sexual dysfunction and
sedation and with modest weight loss during acute and long-term treatment. No withdrawal syndrome has been linked to discontinuation of bupropion. Although increasingly used as first-line monotherapy, a significant percentage of bupropion use occurs as add-on therapy to other antidepressants, usually SSRIs. Bupropion has been marketed under the name Zyban for use in smoking cessation regimens.

PHARMACOLOGIC ACTIONS

Three formulations of bupropion are available: immediate release (taken three times daily), sustained release (taken twice daily), and extended release (taken once daily). The different versions of the drug contain the same active ingredient but differ in their pharmacokinetics and dosing. There have been reports of inconsistencies in bioequivalence between various branded and generic versions of bupropion. Any changes with this drug in tolerability or clinical efficacy in a patient who had been doing well should prompt an inquiry about whether these changes correspond to a switch to a new formulation.

Immediate-release bupropion is well absorbed from the GI tract. Peak plasma concentrations of bupropion are usually reached within 2 hours of oral administration, and peak levels of the sustained-release version are seen after 3 hours. The mean half-life of the compound is 12 hours, ranging from 8 to 40 hours. Peak levels of extended-release bupropion occur 5 hours after ingestion. This provides a longer time to maximum plasma concentration ($t_{\text{max}}$) but comparable peak and trough plasma concentrations. The 24-hour exposure occurring after administration of the extended-release version of 300 mg once daily is equivalent to that provided by sustained release of 150 mg twice daily. Clinically, this permits the drug to be taken once a day in the morning. Plasma levels are also reduced in the evening, making it less likely for some patients to experience treatment-related insomnia.

The mechanism of action for the antidepressant effects of bupropion is presumed to involve the inhibition of dopamine and norepinephrine reuptake. Bupropion binds to the dopamine transporter in the brain. The effects of bupropion on smoking cessation may be related to its effects on dopamine reward pathways or to inhibition of nicotinic acetylcholine receptors.

THERAPEUTIC INDICATIONS

Depression

Although overshadowed by the SSRIs as first-line treatment for major depression, the therapeutic efficacy of bupropion in depression is well established in both outpatient and inpatient settings. Observed rates of response and remission are comparable to those seen with the SSRIs. Bupropion has been found to prevent seasonal major depressive episodes in patients with a history of seasonal pattern or affective disorder.

Smoking Cessation
As the brand name Zyban, bupropion is indicated for use in combination with behavioral modification programs for smoking cessation. It is intended to be used in patients who are highly motivated and who receive some form of structured behavioral support. Bupropion is most effective when combined with nicotine substitutes (Nicoderm, Nicotrol).

**Bipolar Disorders**

Bupropion is less likely than tricyclic antidepressants to precipitate mania in persons with bipolar I disorder and less likely than other antidepressants to exacerbate or induce rapid-cycling bipolar II disorder; however, the evidence about use of bupropion in the treatment of patients with bipolar disorder is limited.

**Attention-Deficit/Hyperactivity Disorder**

Bupropion is used as a second-line agent, after the sympathomimetics, for treatment of attention-deficit/hyperactivity disorder (ADHD). It has not been compared with proven ADHD medications such as methylphenidate (Ritalin) or atomoxetine (Strattera) for childhood and adult ADHD. Bupropion is an appropriate choice for persons with comorbid ADHD and depression or persons with comorbid ADHD, conduct disorder, or substance abuse. It may also be considered for use in patients who develop tics when treated with psychostimulants.

**Cocaine Detoxification**

Bupropion may be associated with a euphoric feeling; thus, it may be contraindicated in persons with histories of substance abuse. However, because of its dopaminergic effects, bupropion has been explored as a treatment to reduce the cravings for cocaine in persons who have withdrawn from the substance. Results have been inconclusive, with some patients showing a reduction in drug craving and others finding their cravings increased.

**Hypoactive Sexual Desire Disorder**

Bupropion is often added to drugs such as SSRIs to counteract sexual side effects and may be helpful as a treatment for nondepressed individuals with hypoactive sexual desire disorder. Bupropion may improve sexual arousal, orgasm completion, and sexual satisfaction.

**PRECAUTIONS AND ADVERSE REACTIONS**

Headache, insomnia, dry mouth, tremor, and nausea are the most common side effects. Restlessness, agitation, and irritability may also occur. Patients with severe anxiety or panic disorder should not be prescribed bupropion. Most likely because of its potentiating effects on dopaminergic neurotransmission, bupropion can cause psychotic
symptoms, including hallucinations, delusions, and catatonia, as well as delirium. Most notable about bupropion is the absence of significant drug-induced orthostatic hypotension, weight gain, daytime drowsiness, and anticholinergic effects. Some persons, however, may experience dry mouth or constipation and weight loss. Hypertension may occur in some patients, but bupropion causes no other significant cardiovascular or clinical laboratory changes. Bupropion exerts indirect sympathomimetic activity, producing positive inotropic effects in human myocardium, an effect that may reflect catecholamine release. Some patients experience cognitive impairment, most notably word-finding difficulties.

Concern about seizure has deterred some physicians from prescribing bupropion. The risk of seizure is dose dependent. Studies show that at dosages of 300 mg a day or less of sustained-release bupropion, the incidence of seizures is 0.05 percent, which is no worse than the incidence of seizures with other antidepressants. The risk of seizures increases to about 0.1 percent with dosages of 400 mg a day.

Changes in electroencephalographic (EEG) waveforms have been reported to be associated with bupropion use. About 20 percent of individuals treated with bupropion exhibit spike waves, sharp waves, and focal slowing. The likelihood of women having sharp waves is higher than for men. The presence of these waveforms in individuals taking a medication known to lower the seizure threshold may be a risk factor for developing seizures. Other risk factors for seizures include a history of seizures, use of alcohol, recent benzodiazepine withdrawal, organic brain disease, head trauma, or pretreatment epileptiform discharges on EEG.

The use of bupropion by pregnant women is not associated with specific risk of increased rate of birth defects. Bupropion is secreted in breast milk, so the use of bupropion in nursing women should be based on the clinical circumstances of the patient and the judgment of the clinician.

Few deaths have been reported after overdoses of bupropion. Poor outcomes are associated with cases of huge doses and mixed-drug overdoses. Seizures occur in about one-third of all overdoses and are dose dependent, with those having seizures ingesting a significantly higher median dose. Fatalities can involve uncontrollable seizures, sinus bradycardia, and cardiac arrest. Symptoms of poisoning most often involve seizures, sinus tachycardia, hypertension, GI symptoms, hallucinations, and agitation. All seizures are typically brief and self-limited. In general, however, bupropion is safer in overdose cases than are other antidepressants except perhaps SSRIs.

DRUG INTERACTIONS

Given the fact that bupropion is frequently combined with SSRIs or venlafaxine, potential interactions are significant. Bupropion has been found to have an effect on the pharmacokinetics of venlafaxine. One study noted a significant increase in venlafaxine levels and a consequent decrease in its main metabolite O-desmethylvenlafaxine during combined treatment with sustained-release bupropion. Bupropion hydroxylation is weakly inhibited by venlafaxine. No significant changes in plasma levels of the SSRIs
paroxetine and fluoxetine have been reported. However, few case reports indicate that the combination of bupropion and fluoxetine (Prozac) may be associated with panic, delirium, or seizures. Bupropion in combination with lithium (Eskalith) may rarely cause CNS toxicity, including seizures.

Because of possibility of inducing a hypertensive crisis, bupropion should not be used concurrently with monoamine oxidase inhibitors (MAOIs). At least 14 days should pass after the discontinuation of an MAOI before initiating treatment with bupropion. In some cases, the addition of bupropion may permit persons taking antiparkinsonian medications to lower the doses of their dopaminergic drugs. However, delirium, psychotic symptoms, and dyskinetic movements may be associated with the coadministration of bupropion and dopaminergic agents such as levodopa (Larodopa), pergolide (Permax), ropinirole (Requip), pramipexole (Mirapex), amantadine (Symmetrel), and bromocriptine (Parlodel). Sinus bradycardia may occur when bupropion is combined with metoprolol.

Carbamazepine (Tegretol) may decrease plasma concentrations of bupropion, and bupropion may increase plasma concentrations of valproic acid (Depakene).

In vitro biotransformation studies of bupropion have found that formation of a major active metabolite, hydroxybupropion, is mediated by CYP2B6. Bupropion has a significant inhibitory effect on CYP2D6.

LABORATORY INTERFERENCES
A report has appeared indicating that bupropion may give a false-positive result on urinary amphetamine screens. No other reports have appeared of laboratory interferences clearly associated with bupropion treatment. Clinically nonsignificant changes in the electrocardiogram (premature beats and nonspecific ST-T changes) and decreases in the white blood cell count (by about 10 percent) have been reported in a small number of persons.

DOSAGE AND CLINICAL GUIDELINES
Immediate-release bupropion is available in 75-, 100-, and 150-mg tablets. Sustained-release bupropion is available in 100-, 150-, 200-, and 300-mg tablets. Extended-release bupropion comes in 150- and 300-mg strengths.

There have been problems associated with one of the extended-release generic versions called Budeprion XL 300-mg tablets, which was found not to be therapeutically equivalent to Wellbutrin XL 300 mg and was removed from the market.

Initiation of immediate-release bupropion in the average adult person should be 75 mg orally twice a day. On the fourth day of treatment, the dosage can be increased to 100 mg three times a day. Because 300 mg is the recommended dose, the person should be maintained on this dose for several weeks before increasing it further. The maximum dosage, 450 mg a day, should be given as 150 mg three times a day. Because of the risk of seizures, increases in dose should never exceed 100 mg in a 3-day period; a single dose of immediate-release bupropion should never exceed 150 mg, and the total daily
dosage should not exceed 450 mg. The maximum of 400 mg of the sustained-release version should be used as a twice-a-day regimen of either 200 mg twice daily or 300 mg in the morning and 100 mg in the afternoon. A starting dosage of the sustained-release version, 100 mg once a day, can be increased to 100 mg twice a day after 4 days. Then 150 mg twice a day may be used. A single dose of sustained-release bupropion should never exceed 300 mg. The maximum dosage is 200 mg twice a day of the immediate-release or extended-release formulations. An advantage of the extended-release preparation is that after appropriate titration, a total of 450 mg can be given all at once in the morning.

For smoking cessation, the patient should start taking 150 mg a day of sustained-release bupropion 10 to 14 days before quitting smoking. On the fourth day, the dosage should be increased to 150 mg twice daily. Treatment generally lasts 7 to 12 weeks.

**References**

**29.11 Buspirone**

Buspirone hydrochloride (BuSpar) is classified as an azapirone and is chemically distinct
from other psychotropic agents. It acts on two types of receptors, serotonin (5-HT) and 
dopamine (D). It has high affinity for the 5-HT$_{1A}$ serotonin receptor, acting as an 
agonist or partial agonist, and moderate affinity for the D$_2$ dopamine receptor, acting 
as both an agonist and an antagonist. The approved indication for this psychotropic 
drug is for the treatment of GAD. It was initially believed to be a better alternative to 
the benzodiazepine drug group because buspirone does not possess anticonvulsant and 
muscle relaxant effects. Reports continue to appear that some patients benefit from the 
addition of buspirone to their antidepressant regimen. Its use in this role is more 
common than its use as an anxiolytic. Interestingly, the antidepressant drug vilazodone 
(Viibryd) inhibits 5-HT reuptake and acts as a 5-HT$_{1A}$ receptor partial agonist.

**PHARMACOLOGIC ACTIONS**

Buspirone is well absorbed from the GI tract, but absorption is delayed by food 
ingestion. Peak plasma levels are achieved 40 to 90 minutes after oral administration. 
At doses of 10 to 40 mg, single-dose linear pharmacokinetics are observed. Nonlinear 
pharmacokinetics are observed after multiple doses. Because of its short half-life (2 to 11 
hours), buspirone is dosed three times daily. An active metabolite of buspirone, 1-
pyrimidinylpiperazine (1-PP), is about 20 percent less potent than buspirone but is up to 
30 percent more concentrated in the brain than the parent compound. The elimination 
half-life of 1-PP is 6 hours.

Buspirone has no effect on the GABA-associated chloride ion channel or the serotonin 
reuptake transporter, targets of other drugs that are effective in GAD. Buspirone also 
has activity at 5-HT$_2$ and dopamine type 2 (D$_2$) receptors, although the significance of 
the effects at these receptors is unknown. At D$_2$ receptors, it has properties of both an 
agonist and an antagonist.

**THERAPEUTIC INDICATIONS**

**Generalized Anxiety Disorder**

Buspirone is a narrow-spectrum antianxiety agent with demonstrated efficacy only in 
the treatment of GAD. In contrast to the SSRIs or venlafaxine, buspirone is not effective 
in the treatment of panic disorder, OCD, or social phobia. Buspirone, however, has an 
advantage over these agents in that it does not typically cause sexual dysfunction or 
weight gain.

Some evidence suggests that compared with benzodiazepines, buspirone is generally 
more effective for symptoms of anger and hostility, equally effective for psychic 
symptoms of anxiety, and less effective for somatic symptoms of anxiety. The full 
benefit of buspirone is evident only at dosages above 30 mg a day. Compared with the 
benzodiazepines, buspirone has a delayed onset of action and lacks any euphoric effect. 
Unlike benzodiazepines, buspirone has no immediate effects, and patients should be told 
that a full clinical response may take 2 to 4 weeks. If an immediate response is needed,
patients can be started on a benzodiazepine and then withdrawn from the drug after buspirone’s effects begin. Sometimes the sedative effects of benzodiazepines, which are not found with buspirone, are desirable; however, these sedative effects may cause impaired motor performance and cognitive deficits.

Other Disorders

Many other clinical uses of buspirone have been reported, but most have not been confirmed in controlled trials. Evidence of the efficacy of high-dosage buspirone (30 to 90 mg a day) for depressive disorders is mixed. Buspirone appears to have weak antidepressant activity, which has led to its use as an augmenting agent in patients who have failed standard antidepressant therapy. In a large study, buspirone augmentation of SSRIs worked as well as other commonly used strategies. Buspirone is sometimes used to augment SSRIs in the treatment of OCD. There are reports that buspirone may be beneficial against the increased arousal and flashbacks associated with posttraumatic stress disorder.

Because buspirone does not act on the GABA–chloride ion channel complex, the drug is not recommended for the treatment of withdrawal from benzodiazepines, alcohol, or sedative–hypnotic drugs, except as treatment of comorbid anxiety symptoms.

Scattered trials suggest that buspirone reduces aggression and anxiety in persons with organic brain disease or traumatic brain injury. It is also used for SSRI-induced bruxism and sexual dysfunction, nicotine craving, and ADHD.

PRECAUTIONS AND ADVERSE REACTIONS

Buspirone does not cause weight gain, sexual dysfunction, discontinuation symptoms, or significant sleep disturbance. It does not produce sedation or cognitive and psychomotor impairment. The most common adverse effects of buspirone are headache, nausea, dizziness, and (rarely) insomnia. No sedation is associated with buspirone. Some persons may report a minor feeling of restlessness, although that symptom may reflect an incompletely treated anxiety disorder. No deaths have been reported from overdoses of buspirone, and the median lethal dose is estimated to be 160 to 550 times the recommended daily dose. Buspirone should be used with caution by persons with hepatic and renal impairment, pregnant women, and nursing mothers. Buspirone can be used safely by the elderly.

DRUG INTERACTIONS

The coadministration of buspirone and haloperidol (Haldol) results in increased blood concentrations of haloperidol. Buspirone should not be used with MAOIs to avoid hypertensive episodes, and a 2-week washout period should pass between the discontinuation of MAOI use and the initiation of treatment with buspirone. Drugs or foods that inhibit CYP3A4, for example, erythromycin (E-mycin), itraconazole (Sporanox), nefazodone (Serzone), and grapefruit juice, increase buspirone plasma
LABORATORY INTERFERENCES

Single doses of buspirone can cause transient elevations in growth hormone, prolactin, and cortisol concentrations, although the effects are not clinically significant.

DOSAGE AND CLINICAL GUIDELINES

Buspirone is available in single-scored 5- and 10-mg tablets and triple-scored 15- and 30-mg tablets; treatment is usually initiated with either 5 mg orally three times daily or 7.5 mg orally twice daily. The dosage can be raised 5 mg every 2 to 4 days to the usual dosage range of 15 to 60 mg a day.

Buspirone should not be used in patients with past hypersensitivity to buspirone, in cases of diabetes-associated metabolic acidosis, or in patients with severely compromised liver or renal function.

Switching from a Benzodiazepine to Buspirone

Buspirone is not cross-tolerant with benzodiazepines, barbiturates, or alcohol. A common clinical problem, therefore, is how to initiate buspirone therapy in a person who is currently taking benzodiazepines. There are two alternatives. First, the clinician can start buspirone treatment gradually while the benzodiazepine is being withdrawn. Second, the clinician can start buspirone treatment and bring the person up to a therapeutic dosage for 2 to 3 weeks while the person is still receiving the regular dosage of the benzodiazepine and then slowly taper the benzodiazepine dosage. Patients who have received benzodiazepines in the past, especially in recent months, may find that buspirone is not as effective as the benzodiazepines in the treatment of their anxiety. This might be explained by the absence of the immediate mildly euphoric and sedative effects of the benzodiazepines. The coadministration of buspirone and benzodiazepines may be effective in the treatment of persons with anxiety disorders who have not responded to treatment with either drug alone.

29.12 Calcium Channel Blockers

The intracellular calcium ion regulates activity of multiple neurotransmitters such as serotonin and dopamine, and that action may account for its role as a treatment in mood disorders. Calcium channel inhibitors are used in psychiatry as antimanic agents for persons who are refractory to or cannot tolerate treatment with first-line mood-stabilizing agents such as lithium (Eskalith), carbamazepine (Tegretol), and divalproex (Depakote). Calcium channel inhibitors include nifedipine (Procardia, Adalat), nimodipine (Nimotop), isradipine (DynaCirc), amlodipine (Norvasc, Lotrel), nicardipine (Cardene), nisoldipine (Sular), nitrendipine, and verapamil (Calan). They are used for control of mania and ultradian bipolar disorder (mood cycling in less than 24 hours).

The results of a large genetic study have rekindled interest in the potential clinical uses of calcium channel blockers (CCBs). Two genome-wide findings implicated genes encoding L-type voltage-gated calcium channel subunits as susceptibility genes for bipolar disorder, schizophrenia, major depressive disorder, ADHD, and autism.

PHARMACOLOGIC ACTIONS

The calcium channel inhibitors are nearly completely absorbed after oral use, with significant first-pass hepatic metabolism. Considerable intraindividual and interindividual variations are seen in the plasma concentrations of the drugs after a single dose. Peak plasma levels of most of these agents are achieved within 30 minutes. Amlodipine does not reach peak plasma levels for about 6 hours. The half-life of verapamil after the first dose is 2 to 8 hours; the half-life increases to 5 to 12 hours after the first few days of therapy. The half-lives of the other CCBs range from 1 to 2 hours for nimodipine and isradipine to 30 to 50 hours for amlodipine (Table 29.12-1).
The primary mechanism of action of CCBs in bipolar illness is not known. The calcium channel inhibitors discussed in this section inhibit the influx of calcium into neurons through L-type (long-acting) voltage-dependent calcium channels.

### THERAPEUTIC INDICATIONS

#### Bipolar Disorder

Nimodipine and verapamil have been demonstrated to be effective as maintenance therapy in persons with bipolar illness. Patients who respond to lithium appear to also respond to treatment with verapamil. Nimodipine may be useful for ultradian cycling and recurrent brief depression. The clinician should begin treatment with a short-acting drug such as nimodipine or isradipine, beginning with a low dosage and increasing the dosage every 4 to 5 days until a clinical response is seen or adverse effects appear. When symptoms are controlled, a longer acting drug, such as amlodipine, can be substituted as maintenance therapy. Failure to respond to verapamil does not exclude a favorable response to one of the other drugs. Verapamil has been shown to prevent antidepressant-induced mania. The CCBs can be combined with other agents, such as carbamazepine, in patients who are partial responders to monotherapy.

#### Depression

None of the CCBs is effective as treatment for depression and may in fact prevent response to antidepressants.

#### Other Psychiatric Indications

Nifedipine is used to treat hypertensive crises associated with the use of MAOIs. Isradipine may reduce the subjective response to methamphetamine. Calcium channel inhibitors may be beneficial in Tourette’s disorder, Huntington’s disease, panic disorder, intermittent explosive disorder, and tardive dyskinesia.

#### Other Medical Uses

These drugs have been used to treat medical conditions such as angina, hypertension, and others. The following table provides a summary of the pharmacokinetic and pharmacotherapeutic properties of the CCBs discussed in this section:

Table adapted from Robert M. Post, MD.
migraine headaches, Raynaud’s phenomenon, esophageal spasm, premature labor, and headache. Verapamil has antiarrhythmic activity and has been used to treat supraventricular arrhythmias.

PRECAUTIONS AND ADVERSE REACTIONS

The most common adverse effects associated with calcium channel inhibitors are those attributable to vasodilation: dizziness, headache, tachycardia, nausea, dysesthesias, and peripheral edema. Verapamil and diltiazem (Cardizem) in particular can cause hypotension, bradycardia, and atrioventricular heart block, which necessitate close monitoring and sometimes discontinuation of the drugs. In all patients with cardiovascular disease, the drugs should be used with caution. Other common adverse effects include constipation, fatigue, rash, coughing, and wheezing. Adverse effects noted with diltiazem include hyperactivity, akathisia, and parkinsonism; with verapamil, delirium, hyperprolactinemia, and galactorrhea; with nimodipine, subjective sense of chest tightness and skin flushing; and with nifedipine, depression. The drugs have not been evaluated for safety in pregnant women and are best avoided. Because the drugs are secreted in breast milk, nursing mothers should also avoid the drugs.

DRUG INTERACTIONS

All CCBs have a potential for drug–drug interactions. The types and risks of these interactions vary by compound. Verapamil raises serum levels of carbamazepine, digoxin, and other CYP3A4 substrates. Verapamil and diltiazem but not nifedipine have been reported to precipitate carbamazepine-induced neurotoxicity. Calcium channel inhibitors should not be used by persons taking β-adrenergic receptor antagonists, hypotensives (e.g., diuretics, vasodilators, and angiotensin-converting enzyme inhibitors), or antiarrhythmic drugs (e.g., quinidine and digoxin) without consultation with an internist or cardiologist. Cimetidine (Tagamet) has been reported to increase plasma concentrations of nifedipine and diltiazem. Some patients who are treated with lithium and calcium channel inhibitors concurrently may be at increased risk for the signs and symptoms of neurotoxicity, and deaths have occurred.

LABORATORY INTERFERENCES

No known laboratory interferences are associated with the use of calcium channel inhibitors.

DOSAGE AND CLINICAL GUIDELINES

Verapamil is available in 40-, 80-, and 120-mg tablets; 120-, 180-, and 240-mg sustained-release tablets; and 100-, 120-, 180-, 200-, 240-, 300-, and 360-mg sustained-release capsules. The starting dosage is 40 mg orally three times a day and can be increased in increments every 4 to 5 days up to 80 to 120 mg three times a day. The patient’s blood pressure, pulse, and electrocardiogram (in patients older than 40 years
old or with a history of cardiac illness) should be routinely monitored.

Nifedipine is available in 10- and 20-mg capsules and 30-, 60-, and 90-mg extended-release tablets. Administration should be started at 10 mg orally three or four times a day and can be increased up to a maximum dosage of 120 mg a day.

Nimodipine is available in 30-mg capsules. It has been used at 60 mg every 4 hours for ultra–rapid-cycling bipolar disorder and sometimes briefly at up to 630 mg per day.

Isradipine is available in 2.5- and 5-mg capsules, with a maximum of 20 mg/day. An extended-release formulation of isradipine has been discontinued.

Amlodipine is available in 2.5-, 5-, and 10-mg tablets. Administration should start at 5 mg once at night and can be increased to a maximum dosage of 10 to 15 mg a day.

Diltiazem is available in 30-, 60-, 90-, and 120-mg tablets; 60-, 90-, 120-, 180-, 240-, 300-, and 360-mg extended-release capsules; and 60-, 90-, 120-, 180-, 240-, 300-, and 360-mg extended-release tablets. Administration should start with 30 mg orally four times a day and can be increased up to a maximum of 360 mg a day.

Elderly persons are more sensitive to the calcium channel inhibitors than are younger adults. No specific information is available regarding the use of the agents for children.

References

29.13 Carbamazepine and Oxcarbazepine
Carbamazepine (Tegretol) possesses some structural similarity to the tricyclic antidepressant imipramine (Tofranil). It was approved for use in the United States for the treatment of trigeminal neuralgia in 1968 and for temporal lobe epilepsy (complex partial seizures) in 1974. Interestingly, carbamazepine was first synthesized as a potential antidepressant, but because of its atypical profile in a number of animal models, it was initially developed for use in pain and seizure disorders. It is now recognized in most guidelines as a second-line mood stabilizer useful in the treatment and prevention of both phases of bipolar affective disorder. A long-acting sustained release formulation (Equetro) was approved by the U.S. Food and Drug Administration (FDA) for the treatment of acute mania in 2002.

An analog of carbamazepine, oxcarbazepine (Trileptal), was marketed as an antiseizure medication in the United States in 2000, after being used as a treatment for pediatric epilepsy in Europe since 1990. Because of its similarity to carbamazepine, many clinicians began to use it as a treatment for patients with bipolar disorder. Despite some reports that oxcarbazepine has mood-stabilizing properties, this has not been confirmed in large, placebo-controlled trials.

**CARBAMAZEPINE**

**Pharmacologic Actions**

Absorption of carbamazepine is slow and unpredictable. Food enhances absorption. Peak plasma concentrations are reached 2 to 8 hours after a single dose, and steady-state levels are reached after 2 to 4 days on a steady dosage. It is 70 to 80 percent protein bound. The half-life of carbamazepine ranges from 18 to 54 hours, with an average of 26 hours. However, with chronic administration, the half-life of carbamazepine decreases to an average of 12 hours. This results from induction of hepatic CYP450 enzymes by carbamazepine, specifically autoinduction of carbamazepine metabolism. The induction of hepatic enzymes reaches its maximum level after about 3 to 5 weeks of therapy.

The pharmacokinetics of carbamazepine are different for two long-acting preparations of carbamazepine, each of which uses slightly different technology. One formulation, Tegretol XR, requires food to ensure normal gastrointestinal (GI) transit time. The other preparation, Carbatrol, relies on a combination of intermediate, extended-release, and very slow release beads, making it suitable for bedtime administration.

Carbamazepine is metabolized in the liver, and the 10,11-epoxide metabolite is active as an anticonvulsant. Its activity in the treatment of bipolar disorders is unknown. Long-term use of carbamazepine is associated with an increased ratio of the epoxide to the parent molecule.

The anticonvulsant effects of carbamazepine are thought to be mediated mainly by binding to voltage-dependent sodium channels in the inactive state and prolonging their inactivation. This secondarily reduces voltage-dependent calcium channel activation and, thus, synaptic transmission. Additional effects include reduction of currents through...
N-methyl-D-aspartate (NMDA) glutamate-receptor channels, competitive antagonism of adenosine $\alpha_1$-receptors, and potentiation of central nervous system (CNS) catecholamine neurotransmission. Whether any or all of these mechanisms also result in mood stabilization is not known.

**Therapeutic Indications**

**Bipolar Disorder**

**ACUTE MANIA.** The acute antimanic effects of carbamazepine are typically evident within the first several days of treatment. About 50 to 70 percent of all persons respond within 2 to 3 weeks of initiation. Studies suggest that carbamazepine may be especially effective in persons who are not responsive to lithium (Eskalith), such as persons with dysphoric mania, rapid cycling, or a negative family history of mood disorders. The antimanic effects of carbamazepine can be, and often are, augmented by concomitant administration of lithium, valproic acid (Depakene), thyroid hormones, dopamine receptor antagonists (DRAs), or serotonin-dopamine antagonists (SDAs). Some persons may respond to carbamazepine but not lithium or valproic acid and vice versa.

**PROPHYLAXIS.** Carbamazepine is effective in preventing relapses, particularly among patients with bipolar II disorder and schizoaffective disorder, and dysphoric mania.

**ACUTE DEPRESSION.** A subgroup of treatment-refractory patients with acute depression responds well to carbamazepine. Patients with more severe episodic and less chronic depression seem to be better responders to carbamazepine. Nevertheless, carbamazepine remains an alternative drug for depressed persons who have not responded to conventional treatments, including electroconvulsive therapy (ECT).

**Other Disorders.** Carbamazepine helps to control symptoms associated with acute alcohol withdrawal, although benzodiazepines are more effective in this population. Carbamazepine has been suggested as a treatment for the paroxysmal recurrent component of posttraumatic stress disorder (PTSD). Uncontrolled studies suggest that carbamazepine is effective in controlling impulsive, aggressive behavior in nonpsychotic persons of all ages, including children and elderly persons. Carbamazepine is also effective in controlling nonacute agitation and aggressive behavior in patients with schizophrenia and schizoaffective disorder. Persons with prominent positive symptoms (e.g., hallucinations) may be likely to respond, as are persons who display impulsive aggressive outbursts.

**Precautions and Adverse Reactions**

Carbamazepine is relatively well tolerated. Mild GI (nausea, vomiting, gastric distress, constipation, diarrhea, and anorexia) and CNS (ataxia, drowsiness) side effects are the most common. The severity of these adverse effects is reduced if the dosage of carbamazepine is increased slowly and kept at the minimal effective plasma
concentration. In contrast to lithium and valproate (other drugs used to manage bipolar disorder), carbamazepine does not appear to cause weight gain. Because of the phenomena of autoinduction, with consequent reductions in carbamazepine concentrations, side effect tolerability may improve over time. Most of the adverse effects of carbamazepine are correlated with plasma concentrations above 9 μg/mL. The rarest but most serious adverse effects of carbamazepine are blood dyscrasias, hepatitis, and serious skin reactions (Table 29.13-1).

Blood Dyscrasias. The drug’s hematologic effects are not dose related. Severe blood dyscrasias (aplastic anemia, agranulocytosis) occur in about 1 in 125,000 persons treated with carbamazepine. There does not appear to be a correlation between the degree of benign white blood cell (WBC) suppression (leukopenia), which is seen in 1 to 2 percent of persons, and the emergence of life-threatening blood dyscrasias. Persons should be warned that the emergence of such symptoms as fever, sore throat, rash, petechiae, bruising, and easy bleeding can potentially herald a serious dyscrasia, and they should seek medical evaluation immediately. Routine hematologic monitoring in carbamazepine-treated persons is recommended at 3, 6, 9, and 12 months. If there is no significant evidence of bone marrow suppression by that time, many experts would reduce the interval of monitoring. However, even assiduous monitoring may fail to detect severe blood dyscrasias before they cause symptoms.

Hepatitis. Within the first few weeks of therapy, carbamazepine can cause both hepatitis associated with increases in liver enzymes, particularly transaminases, and cholestasis associated with elevated bilirubin and alkaline phosphatase. Mild transaminase elevations warrant observation only, but persistent elevations more than three times the upper limit of normal indicate the need to discontinue the drug. Hepatitis can recur if the drug is reintroduced to the person and can result in death.

Dermatologic Effects. About 10 to 15 percent of those treated with carbamazepine develop a benign maculopapular rash within the first 3 weeks of treatment. Stopping the medication usually leads to resolution of the rash. Some patients may experience life-threatening dermatologic syndromes, including exfoliative dermatitis, erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. The possible emergence of these serious dermatologic problems causes most
Clinicians to discontinue carbamazepine use in people who develop any type of rash. The risk of drug rash is about equal between valproic acid and carbamazepine in the first 2 months of use but is subsequently much higher for carbamazepine. If carbamazepine seems to be the only effective drug for a person who has a benign rash with carbamazepine treatment, a retrial of the drug can be undertaken. Many patients can be rechallenged without reemergence of the rash. Pretreatment with prednisone (Deltasone; 40 mg a day) may suppress the rash, although other symptoms of an allergic reaction (e.g., fever and pneumonitis) may develop even with steroid pretreatment.

**Renal Effects.** Carbamazepine is occasionally used to treat diabetes insipidus not associated with lithium use. This activity results from direct or indirect effects at the vasopressin receptor. It may also lead to the development of hyponatremia and water intoxication in some patients, particularly elderly persons, or when used in high doses.

**Other Adverse Effects.** Carbamazepine decreases cardiac conduction (although less than the tricyclic drugs do) and can thus exacerbate preexisting cardiac disease. Carbamazepine should be used with caution in persons with glaucoma, prostatic hypertrophy, diabetes, or a history of alcohol abuse. Carbamazepine occasionally activates vasopressin receptor function, which results in a condition resembling the syndrome of secretion of inappropriate antidiuretic hormone, characterized by hyponatremia and, rarely, water intoxication. This is the opposite of the renal effects of lithium (i.e., nephrogenic diabetes insipidus). Augmentation of lithium with carbamazepine does not reverse the lithium effect, however. Emergence of confusion, severe weakness, or headache in a person taking carbamazepine should prompt measurement of serum electrolytes.

Carbamazepine use rarely elicits an immune hypersensitivity response consisting of fever, rash, eosinophilia, and possibly fatal myocarditis.

Cleft palate, fingernail hypoplasia, microcephaly, and spina bifida in infants may be associated with the maternal use of carbamazepine during pregnancy. Pregnant women should not use carbamazepine unless absolutely necessary. All women with childbearing potential should take 1 to 4 mg of folic acid daily even if they are not trying to conceive. Carbamazepine is secreted in breast milk.

**Drug Interactions**

Carbamazepine decreases serum concentrations of numerous drugs as a result of prominent induction of hepatic CYP3A4 (Table 29.13-2). Monitoring for a decrease in clinical effects is frequently indicated. Carbamazepine can decrease the blood concentrations of oral contraceptives, resulting in breakthrough bleeding and uncertain prophylaxis against pregnancy. Carbamazepine should not be administered with monoamine oxidase inhibitors (MAOIs), which should be discontinued at least 2 weeks before initiating treatment with carbamazepine. Grapefruit juice inhibits the hepatic metabolism of carbamazepine. When carbamazepine and valproate are used in
combination, the dosage of carbamazepine should be decreased because valproate displaces carbamazepine binding on proteins, and the dosage of valproate may need to be increased.

### Laboratory Interferences

Circulating levels of thyroxine and triiodothyronine are associated with a decrease in
thyroid-stimulating hormone and may be associated with treatment. Carbamazepine is also associated with an increase in total serum cholesterol, primarily by increasing high-density lipoproteins. The thyroid and cholesterol effects are not clinically significant. Carbamazepine may interfere with the dexamethasone (Decadron) suppression test and may also cause false-positive pregnancy test results.

**Dosing and Administration**

The target dose for antimanic activity is 1,200 mg a day, although this varies considerably. Immediate-release carbamazepine needs to be taken three or four times a day, which leads to lapses in compliance. Extended-release formulations are thus preferred because they can be taken once or twice a day. One form of extended-release carbamazepine, Carbatrol, comes as 100-, 200-, and 300-mg capsules. Another form, Equetro, is identical to Carbatrol and is marketed as a treatment for bipolar disorder. These capsules contain tiny beads with three different types of coatings so they dissolve at different times. Capsules should not be crushed or chewed. The contents can be sprinkled over food, however, without affecting the extended-release qualities. This formulation can be taken either with or without meals. The entire daily dose can be given at bedtime. The rate of absorption is faster when it is given with a high-fat meal. Another extended-release form of carbamazepine, Tegretol XR, uses a different drug-delivery system than Carbatrol. It is available in 100-, 200-, and 300-mg tablets.

Preexisting hematologic, hepatic, and cardiac diseases can be relative contraindications for carbamazepine treatment. Persons with hepatic disease require only one third to one half the usual dosage; the clinician should be cautious about raising the dosage in such persons and should do so only slowly and gradually. The laboratory examination should include a complete blood count with platelet count, liver function tests, serum electrolytes, and an electrocardiogram in persons older than 40 years of age or with a preexisting cardiac disease. An electroencephalogram is not necessary before the initiation of treatment, but it may be helpful in some cases for the documentation of objective changes correlated with clinical improvement. Table 29.13-3 presents a brief user’s guide to carbamazepine in bipolar disorder.

---

**Table 29.13-3**

Carbamazepine in Bipolar Illness: A Brief User’s Guide
Routine Laboratory Monitoring

Serum levels for antimanic efficacy have not been established. The anticonvulsant blood concentration range for carbamazepine is 4 to 12 μg/mL, and this range should be reached before determining that carbamazepine is not effective in the treatment of a mood disorder. A clinically insignificant suppression of the WBC count commonly occurs during carbamazepine treatment. This benign decrease can be reversed by adding lithium, which enhances colony-stimulating factor. Potential serious hematologic effects of carbamazepine, such as pancytopenia, agranulocytosis, and aplastic anemia, occur in about 1 in 125,000 patients. Complete laboratory blood assessments may be performed every 2 weeks for the first 2 months of treatment and quarterly thereafter, but the FDA has revised the package insert for carbamazepine to suggest that blood monitoring be performed at the discretion of the physician. Patients should be informed that fever, sore throat, rash, petechiae, bruising, or unusual bleeding may indicate a hematologic problem and should prompt immediate notification of a physician. This approach is probably more effective than is frequent blood monitoring during long-term treatment. It has also been suggested that liver and renal function tests be conducted quarterly, although the benefit of conducting tests this frequently has been questioned. It seems reasonable, however, to assess hematologic status, along with liver and renal functions whenever a routine examination of the person is being conducted. A monitoring protocol is listed in Table 29.13-4.
Carbamazepine treatment should be discontinued and a consult with a hematologist should be obtained if the following laboratory values are found: total WBC count below 3,000/mm$^3$, erythrocytes below $4.0 \times 10^6$/mm$^3$, neutrophils below 1,500/mm$^3$, hematocrit less than 32 percent, hemoglobin less than 11 g/100 mL, platelet count below 100,000/mm$^3$, reticulocyte count below 0.3 percent, and a serum iron concentration below 150 mg/100 mL.

**OXCARBAZEPINE**

Although structurally related to carbamazepine, the usefulness of oxcarbazepine as a treatment for mania has not been established in controlled trials.

**Pharmacokinetics**

Absorption is rapid and unaffected by food. Peak concentrations occur after about 45 minutes. The elimination half-life of the parent compound is 2 hours, which remains stable over long-term treatment. The monohydroxide has a half-life of 9 hours. Most of the drug’s anticonvulsant activity is presumed to result from this monohydroxy derivative.

**Side Effects**

The most common side effects are sedation and nausea. Less frequent side effects are cognitive impairment, ataxia, diplopia, nystagmus, dizziness, and tremor. In contrast to carbamazepine, oxcarbazepine does not have an increased risk of serious blood dyscrasias, so hematologic monitoring is not necessary. The frequency of benign rash is lower than observed with carbamazepine, and serious rashes are extremely rare. However, about 25 to 30 percent of patients who develop an allergic rash while taking carbamazepine also develop a rash with oxcarbazepine. Oxcarbazepine is more likely to cause hyponatremia than carbamazepine. Approximately 3 to 5 percent of patients taking oxcarbazepine develop this side effect. It is advisable to obtain serum sodium.

---

CBC, complete blood count.
concentrations early in the course of treatment because hyponatremia may be clinically silent. In severe cases, confusion and seizure may occur.

**Dosing and Administration**

Oxcarbazepine dosing for bipolar disorder has not been established. It is available in 150-, 300-, and 600-mg tablets. The dose range may vary from 150 to 2,400 mg per day given in divided doses twice a day. In clinical trials for mania, the doses typically used were from 900 to 1,200 mg per day with a starting dose of 150 or 300 mg at night.

**Drug Interactions**

Drugs such as phenobarbital and alcohol, which induce CYP34A, increase the clearance and reduce oxcarbazepine concentrations. Oxcarbazepine induces CYP3A4/5 and inhibits CYP2C19, which may affect the metabolism of drugs that use that pathway. Women taking oral contraceptives should be told to consult with their gynecologists because oxcarbazepine may reduce concentrations of their contraceptive and thus decrease its efficacy.

**References**

Donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl) are cholinesterase inhibitors used to treat mild to moderate cognitive impairment in dementia of the Alzheimer’s type. They reduce the inactivation of the neurotransmitter acetylcholine and, thus, potentiate cholinergic neurotransmission, which in turn produces a modest improvement in memory and goal-directed thought. Memantine (Namenda) is not a cholinesterase inhibitor, producing its effects through blockade of N-methyl-D-aspartate (NMDA) receptors. Unlike the cholinesterase inhibitors, which are indicated for the mild to moderate stages of Alzheimer’s disease, memantine is indicated for the moderate to severe stages of the disease. Tacrine (Cognex), the first cholinesterase inhibitor to be introduced, is no longer used because of its multiple daily dosing regimens, its potential for hepatotoxicity, and the consequent need for frequent laboratory monitoring. Routine clinical practice often combines a cholinesterase inhibitor with memantine, and recent studies have shown that this combination may provide beneficial response compared with only cholinesterase inhibitor pharmacotherapy.

PHARMACOLOGICAL ACTIONS

Donepezil is absorbed completely from the gastrointestinal (GI) tract. Peak plasma concentrations are reached about 3 to 4 hours after oral dosing. The half-life of donepezil is 70 hours in elderly persons, and it is taken only once daily. Steady-state levels are achieved within about 2 weeks. The presence of stable alcoholic cirrhosis reduces clearance of donepezil by 20 percent. Rivastigmine (Exelon) is rapidly and completely absorbed from the GI tract and reaches peak plasma concentrations in 1 hour, but this is delayed by up to 90 minutes if rivastigmine is taken with food. The half-life of rivastigmine is 1 hour, but because it remains bound to cholinesterases, a single dose is therapeutically active for 10 hours, and it is taken twice daily. Galantamine (Reminyl) is an alkaloid similar to codeine and is extracted from daffodils of the plant Galanthus nivalis. It is readily absorbed, with maximum concentrations reached after 30 minutes to 2 hours. Food decreases the maximum concentration by 25 percent. The elimination half-life of galantamine is approximately 6 hours.

Tacrine (Cognex) is absorbed rapidly from the GI tract. Peak plasma concentrations are reached about 90 minutes after oral dosing. The half-life of tacrine is about 2 to 4 hours, thereby necessitating four-times-daily dosing.

The primary mechanism of action of cholinesterase inhibitors is reversible, nonacetylating inhibition of acetylcholinesterase and butyrylcholinesterase, the enzymes that catabolize acetylcholine in the central nervous system (CNS). The enzyme inhibition increases synaptic concentrations of acetylcholine, especially in the hippocampus and cerebral cortex. Unlike tacrine, which is nonselective for all forms of acetylcholinesterase, donepezil appears to be selectively active within the CNS and has little activity in the periphery. Donepezil’s favorable side effect profile appears to correlate with its lack of inhibition of cholinesterases in the GI tract. Rivastigmine appears to have somewhat more peripheral activity than donepezil and is thus more
likely to cause GI adverse effects than is donepezil.

**THERAPEUTIC INDICATIONS**

Cholinesterase inhibitors are effective for the treatment of mild to moderate cognitive impairment in dementia of the Alzheimer’s type. In long-term use, they slow the progression of memory loss and diminish apathy, depression, hallucinations, anxiety, euphoria, and purposeless motor behaviors. Functional autonomy is less well preserved. Some persons note immediate improvement in memory, mood, psychotic symptoms, and interpersonal skills. Others note little initial benefit but are able to retain their cognitive and adaptive faculties at a relatively stable level for many months. A practical benefit of cholinesterase inhibitor use is a delay or reduction of the need for nursing home placement.

Donepezil and rivastigmine may be beneficial for patients with Parkinson’s disease and Lewy body disease and for treatment of cognitive deficits caused by traumatic brain injury. Donepezil is under study for treatment of mild cognitive impairment that is less severe than that caused by Alzheimer’s disease. People with vascular dementia may respond to acetylcholinesterase inhibitors. Occasionally, cholinesterase inhibitors elicit an idiosyncratic catastrophic reaction, with signs of grief and agitation, which is self-limited after the drug is discontinued. Use of cholinesterase inhibitors to improve cognition by nondemented individuals should be discouraged.

**PRECAUTIONS AND ADVERSE REACTIONS**

**Donepezil**

Donepezil is generally well tolerated at recommended dosages. Fewer than 3 percent of those taking donepezil experience nausea, diarrhea, and vomiting. These mild symptoms are more common with a 10-mg dose than with a 5-mg dose, and when present, they tend to resolve after 3 weeks of continued use. Donepezil may cause weight loss. Donepezil treatment has been infrequently associated with bradycardia, especially in those with underlying cardiac disease. A small number of persons experience syncope.

**Rivastigmine**

Rivastigmine is generally well tolerated, but recommended dosages may need to be scaled back in the initial period of treatment to limit GI and CNS adverse effects. These mild symptoms are more common at dosages above 6 mg a day, and when present, they tend to resolve after the dosage is lowered. The most common adverse effects associated with rivastigmine are nausea, vomiting, dizziness, headache, diarrhea, abdominal pain, anorexia, fatigue, and somnolence. Rivastigmine may cause weight loss, but it does not appear to cause hepatic, renal, hematologic, or electrolyte abnormalities.

**Galantamine**
The most common side effects of galantamine are dizziness, headache, nausea, vomiting, diarrhea, and anorexia. These side effects tend to be mild and transient.

**Tacrine**

Tacrine is the least used of the cholinesterase inhibitors but requires more discussion than the others because it is cumbersome to titrate and use, and it poses the risk of potentially significant elevations in hepatic transaminase levels. These increases occur in 25 to 30 percent of persons. Aside from elevated transaminase levels, the most common specific adverse effects associated with tacrine treatment are nausea, vomiting, myalgia, anorexia, and rash, but only nausea, vomiting, and anorexia have been found to have a clear relation to the dosage. Transaminase elevations characteristically develop during the first 6 to 12 weeks of treatment, and cholinergically mediated events are dosage related.

**Hepatotoxicity.** Tacrine is associated with increases in the plasma activities of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). The ALT measurement is the more sensitive indicator of the hepatic effects of tacrine. About 95 percent of patients who develop elevated ALT serum levels do so in the first 18 weeks of treatment. The average length of time for elevated ALT concentrations to return to normal after stopping tacrine treatment is 4 weeks.

For routine monitoring of hepatic enzymes, AST and ALT activities should be measured weekly for the first 18 weeks, every month for the second 4 months, and every 3 months thereafter. Weekly assessments of AST and ALT should be performed for at least 6 weeks after any increase in dosage. Patients with mildly elevated ALT activity should be monitored weekly and not be rechallenged with tacrine until the ALT activity returns to the normal range. For any patient with elevated ALT activity and jaundice, tacrine treatment should be stopped, and the patient should not be given the drug again.

Table 29.14-1 summarizes the incidence of major adverse side effects associated with each of the cholinesterase inhibitors.

NR, not reported from clinical trial data; incidence less than 5%.

**Drug Interactions**
All cholinesterase inhibitors should be used cautiously with drugs that also possess cholinomimetic activity, such as succinylcholine (Anectine) and bethanechol (Urecholine). The coadministration of cholinesterase inhibitors and drugs that have cholinergic antagonist activity (e.g., tricyclic drugs) is probably counterproductive. Paroxetine (Paxil) has the most marked anticholinergic effects of any of the newer antidepressant and anxiolytic drugs and should be avoided for that reason, as well as its inhibiting effect on the metabolism of some of the cholinesterase inhibitors.

Donepezil undergoes extensive metabolism via both CYP2D6 and 3A4 isozymes. The metabolism of donepezil may be increased by phenytoin (Dilantin), carbamazepine (Tegretol), dexamethasone (Decadron), rifampin (Rifadin), and phenobarbital (Solfoton). Commonly used agents such as paroxetine, ketoconazole (Nizoral), and erythromycin can significantly increase donepezil concentrations. Donepezil is highly protein bound, but it does not displace other protein-bound drugs, such as furosemide (Lasix), digoxin (Lanoxin), or warfarin (Coumadin). Rivastigmine circulates mostly unbound to serum proteins and has no significant drug interactions.

Similar to donepezil, galantamine is metabolized by both CYP2D6 and 3A4 isozymes and thus may interact with drugs that inhibit these pathways. Paroxetine and ketoconazole should be used with great caution.

Laboratory Interferences

No laboratory interferences have been associated with the use of cholinesterase inhibitors.

Dosage and Clinical Guidelines

Before initiation of cholinesterase inhibitor therapy, potentially treatable causes of dementia should be ruled out and the diagnosis of dementia of the Alzheimer’s type established.

Donepezil is available in 5- and 10-mg tablets. Treatment should be initiated at 5 mg each night. If well tolerated and of some discernible benefit after 4 weeks, the dosage should be increased to a maintenance dosage of 10-mg each night. Donepezil absorption is unaffected by meals.

Rivastigmine is available in 1.5-, 3-, 4.5-, and 6-mg capsules. The recommended initial dosage is 1.5 mg twice daily for a minimum of 2 weeks, after which increases of 1.5 mg a day can be made at intervals of at least 2 weeks to a target dosage of 6 mg a day, taken in two equal dosages. If tolerated, the dosage may be further titrated upward to a maximum of 6 mg twice daily. The risk of adverse GI events can be reduced by administration of rivastigmine with food.

Galantamine is available in 4-, 8-, and 16-mg tablets. The suggested dose range is 16 to 32 mg per day given twice a day. The higher dose is actually better tolerated than the lower dose. The initial dosage is 8 mg per day, and after a minimum of 4 weeks, the dose can be raised. All subsequent dosage increases should occur at 4-week intervals and should be based on tolerability.
Tacrine is available in 10-, 20-, 30-, and 40-mg capsules. Before the initiation of tacrine treatment, a complete physical and laboratory examination should be conducted, with special attention to liver function tests and baseline hematologic indexes. Treatment should be initiated at 10 mg four times a day and then raised by increments of 10 mg a dose every 6 weeks up to 160 mg a day; the person’s tolerance of each dosage is indicated by the absence of unacceptable side effects and lack of elevation of ALT activity. Tacrine should be given four times daily—ideally 1 hour before meals because the absorption of tacrine is reduced by about 25 percent when it is taken during the first 2 hours after meals. If tacrine is used, the specific guidelines for tacrine-induced ALT listed above should be followed.

MEMANTINE

Pharmacological Actions
Memantine is well absorbed after oral administration, with peak concentrations reached in about 3 to 7 hours. Food has no effect on the absorption of memantine. Memantine has linear pharmacokinetics over the therapeutic dosage range and has a terminal elimination half-life of about 60 to 80 hours. Plasma protein binding is 45 percent.

Memantine undergoes little metabolism, with the majority (57 to 82 percent) of an administered dose excreted unchanged in urine; the remainder is converted primarily to three polar metabolites: the N-gludantan conjugate, 6-hydroxy memantine, and 1-nitroso-deaminated memantine. These metabolites possess minimal NMDA receptor antagonist activity. Memantine is a low- to moderate-affinity NMDA receptor antagonist. It is thought that overexcitation of NMDA receptors by the neurotransmitter glutamate may play a role in Alzheimer’s disease because glutamate plays an integral role in the neural pathways associated with learning and memory. Excess glutamate overstimulates NMDA receptors to allow too much calcium into nerve cells, leading to the eventual cell death observed in Alzheimer’s disease. Memantine may protect cells against excess glutamate by partially blocking NMDA receptors associated with abnormal transmission of glutamate while allowing for physiologic transmission associated with normal cell functioning.

Therapeutic Indications
Memantine is the only approved therapy in the United States for moderate to severe Alzheimer’s disease.

Precautions and Adverse Reactions
Memantine is safe and well tolerated. The most common adverse effects are dizziness, headache, constipation, and confusion. The use of memantine in patients with severe renal impairment is not recommended. In a documented case of an overdose with up to 400 mg of memantine, the patient experienced restlessness, psychosis, visual
hallucinations, somnolence, stupor, and loss of consciousness. The patient recovered without permanent sequelae.

**Drug Interactions**

In vitro studies conducted with marker substrates of CYP450 enzymes (CYP1A2, 2A6, 2C9, 2D6, 2E1, and 3A4) showed minimal inhibition of these enzymes by memantine. No pharmacokinetic interactions with drugs metabolized by these enzymes are expected. Because memantine is eliminated in part by tubular secretion, coadministration of drugs that use the same renal cationic system, including hydrochlorothiazide triamterene (Dyrenium), cimetidine (Tagamet), ranitidine (Zantac), quinidine, and nicotine, could potentially result in altered plasma levels of both agents. Coadministration of memantine and a combination of hydrochlorothiazide and triamterene did not affect the bioavailability of either memantine or triamterene, and the bioavailability of hydrochlorothiazide decreased by 20 percent.

Urine pH is altered by diet, drugs (e.g., carbonic anhydrase inhibitors, topiramate [Topamax], sodium bicarbonate), and the clinical state of the patient (e.g., renal tubular acidosis or severe infections of the urinary tract). The clearance of memantine is reduced by about 80 percent under alkaline urine conditions at pH 8. Therefore, alterations of urine pH toward the alkaline condition may lead to an accumulation of the drug with a possible increase in adverse effects. Hence, memantine should be used with caution under these conditions.

**Laboratory Interferences**

No laboratory interferences have been associated with the use of memantine.

**Dosage and Clinical Guidelines**

Memantine is available in 5- and 10-mg tablets, with a recommended starting dose of 5 mg daily. The recommended target dose is 20 mg per day. The drug is administered twice daily in separate doses with 5-mg increment increases weekly depending on tolerability.

Patients with mild to moderate disease receiving memantine in combination with a cholinesterase inhibitor have not been found to experience significantly greater benefit in cognition or overall function than those who receive a cholinesterase inhibitor alone.

**REFERENCES**

Disulfiram (Antabuse) and acamprosate (Campral) are drugs used to treat alcohol dependence. Disulfiram has suffered from a reputation as a dangerous medication only suitable for highly motivated and strictly supervised drinkers because of the severe physical reactions the drug causes after drinking. Experience has shown, however, that at recommended doses it is an acceptable and safe medication for dependent drinkers seeking to sustain abstinence. The properties that constitute disulfiram’s main therapeutic effect (i.e., the ability to produce unpleasant symptoms after alcohol intake, also known as disulfiram–alcohol reaction) have created that perception of dangerousness.

In the most severe cases, when disulfiram is combined with alcohol serious clinical conditions can occur. These include respiratory depression, cardiovascular collapse, acute heart failure, convulsions, loss of consciousness, and death in rare cases. These potential complications as well as the development of alternative antialcohol medications have been the limiting factors for the wider use of disulfiram. Unlike disulfiram, acamprosate, the other drug discussed in this section, does not produce aversive side effects. Acamprosate is now prescribed more commonly than disulfiram in outpatient settings, but disulfiram is prescribed more often in inpatient settings because it helps facilitate initial abstinence.

Other drugs that are useful in reducing alcohol consumption include naltrexone (ReVia, Trexan), nalmefene (Revex), topiramate (Topamax), and gabapentin
DISULFIRAM
Pharmacologic Actions
Disulfiram is almost completely absorbed from the gastrointestinal (GI) tract after oral administration. Its half-life is estimated to be 60 to 120 hours. Therefore, 1 or 2 weeks may be needed before disulfiram is totally eliminated from the body after the last dose has been taken.

The metabolism of ethanol proceeds through oxidation via alcohol dehydrogenase to the formation of acetaldehyde, which is further metabolized to acetyl-coenzyme A (acetyl-CoA) by aldehyde dehydrogenase. Disulfiram is an aldehyde dehydrogenase inhibitor that interferes with the metabolism of alcohol by producing a marked increase in blood acetaldehyde concentration. The accumulation of acetaldehyde (to a level up to 10 times higher than occurs in the normal metabolism of alcohol) produces a wide array of unpleasant reactions, called the disulfiram–alcohol reaction, characterized by nausea, throbbing headache, vomiting, hypertension, flushing, sweating, thirst, dyspnea, tachycardia, chest pain, vertigo, and blurred vision. The reaction occurs almost immediately after the ingestion of one alcoholic drink and may last from 30 minutes to 2 hours.

Blood Concentrations in Relation to Action. Plasma concentrations of disulfiram varies among individuals because of a number of factors, most notably age and hepatic function. In general, the severity of disulfiram–alcohol reaction has been shown to be proportional to the amount of the ingested disulfiram and alcohol. Nevertheless, disulfiram plasma levels are rarely obtained in clinical practice. The positive correlation between plasma concentrations of alcohol and the intensity of the reaction is described as follows: in sensitive individuals, as little as 5 to 10 mg per 100 mL increase of the plasma alcohol level may produce mild symptoms; fully developed symptoms occur at alcohol levels of 50 mg per 100 mL; and levels as high as 125 to 150 mg per 100 mL result in loss of consciousness and coma.

Therapeutic Indications
The primary indication for disulfiram use is as an aversive conditioning treatment for alcohol dependence. Either the fear of having a disulfiram–alcohol reaction or the memory of having had one is meant to condition the person not to use alcohol. Usually, describing the severity and the unpleasantness of the disulfiram–alcohol reaction graphically enough discourages the person from imbibing alcohol. Disulfiram treatment should be combined with such treatments as psychotherapy, group therapy, and support groups such as Alcoholics Anonymous (AA). Treatment with disulfiram requires careful monitoring because a person can simply decide not to take the medication.
Precautions and Adverse Reactions

With Alcohol Consumption. The intensity of the disulfiram–alcohol reaction varies with each person. In extreme cases, it is marked by respiratory depression, cardiovascular collapse, myocardial infarction, convulsions, and death. Therefore, disulfiram is contraindicated for persons with significant pulmonary or cardiovascular disease. In addition, disulfiram should be used with caution, if at all, by persons with nephritis, brain damage, hypothyroidism, diabetes, hepatic disease, seizures, polydrug dependence, or an abnormal electroencephalogram. Most fatal reactions occur in persons who take more than 500 mg a day of disulfiram and who consume more than 3 oz of alcohol. The treatment of a severe disulfiram–alcohol reaction is primarily supportive to prevent shock. The use of oxygen, intravenous vitamin C, ephedrine, and antihistamines has been reported to aid in recovery.

Without Alcohol Consumption. The adverse effects of disulfiram in the absence of alcohol consumption include fatigue, dermatitis, impotence, optic neuritis, a variety of mental changes, and hepatic damage. A metabolite of disulfiram inhibits dopamine-β-hydroxylase, the enzyme that metabolizes dopamine into norepinephrine and epinephrine, and thus may exacerbate psychosis in persons with psychotic disorders. Catatonic reactions may also occur.

Drug Interactions
Disulfiram increases the blood concentration of diazepam (Valium), paraldehyde, phenytoin (Dilantin), caffeine, tetrahydrocannabinol (the active ingredient in marijuana), barbiturates, anticoagulants, isoniazid (Nydradzid), and tricyclic drugs. Disulfiram should not be administered concomitantly with paraldehyde because paraldehyde is metabolized to acetaldehyde in the liver.

Laboratory Interferences
In rare instances, disulfiram has been reported to interfere with the incorporation of iodine-131 into protein-bound iodine. Disulfiram may reduce urinary concentrations of homovanillic acid, the major metabolite of dopamine, because of its inhibition of dopamine hydroxylase.

Dosage and Clinical Guidelines
Disulfiram is supplied in 250- and 500-mg tablets. The usual initial dosage is 500 mg a day taken by mouth for the first 1 or 2 weeks followed by a maintenance dosage of 250 mg a day. The dosage should not exceed 500 mg a day. The maintenance dosage range is 125 to 500 mg a day.

Persons taking disulfiram must be instructed that the ingestion of even the smallest amount of alcohol will bring on a disulfiram–alcohol reaction, with all of its unpleasant
effects. In addition, persons should be warned against ingesting any alcohol-containing preparations, such as cough drops, tonics of any kind, and alcohol-containing foods and sauces. Some reactions have occurred in patients who used alcohol-based lotions, toilet water, colognes, or perfumes and inhaled the fumes; therefore, precautions must be explicit and should include any topically applied preparations containing alcohol, such as perfume.

Disulfiram should not be administered until the person has abstained from alcohol for at least 12 hours. Persons should be warned that the disulfiram–alcohol reaction may occur as long as 1 or 2 weeks after the last dose of disulfiram. Persons taking disulfiram should carry identification cards describing the disulfiram–alcohol reaction and listing the name and telephone number of the physician to be called.

ACAMPROSATE
Pharmacologic Actions
Acamprosate’s mechanism of action is not fully understood, but it is thought to antagonize neuronal overactivity related to the actions of the excitatory neurotransmitter glutamate. In part, this may result from antagonism of N-methyl-d-aspartate (NMDA) receptors.

Indications
Acamprosate is used for treating alcohol-dependent individuals seeking to continue to remain alcohol free after they have stopped drinking. Its efficacy in promoting abstinence has not been demonstrated in persons who have not undergone detoxification and who have not achieved alcohol abstinence before beginning treatment.

Precautions and Adverse Effects
Side effects are mostly seen early in treatment and are usually mild and transient in nature. The most common side effects are headache, diarrhea, flatulence, abdominal pain, paresthesias, and various skin reactions. No adverse events occur after abrupt withdrawal of acamprosate, even after long-term use. There is no evidence of addiction to the drug. Patients with severe renal impairment (creatinine clearance of less than 30 mL per minute) should not be given acamprosate.

Drug Interactions
The concomitant intake of alcohol and acamprosate does not affect the pharmacokinetics of either alcohol or acamprosate. Administration of disulfiram or diazepam does not affect the pharmacokinetics of acamprosate. Coadministration of naltrexone with acamprosate produces an increase in concentrations of acamprosate. No adjustment of dosage is recommended in such patients. The pharmacokinetics of
naltrexone and its major metabolite 6-β-naltrexol were unaffected after coadministration with acamprosate. During clinical trials, patients taking acamprosate concomitantly with antidepressants more commonly reported both weight gain and weight loss compared with patients taking either medication alone.

**Laboratory Interferences**

Acamprosate has not been shown to interfere with commonly done laboratory tests.

**Dosage and Clinical Guidelines**

It is important to remember that acamprosate should not be used to treat alcohol withdrawal symptoms. It should only be started after the individual has been successfully weaned off alcohol. Patients should show a commitment to remaining abstinent, and treatment should be part of a comprehensive management program that includes counseling or support group attendance.

Each tablet contains acamprosate calcium 333 mg, which is equivalent to 300 mg of acamprosate. The dose of acamprosate is different for different patients. The recommended dosage is two 333-mg tablets (each dose should total 666 mg) taken three times daily. Although dosing may be done without regard to meals, dosing with meals was used during clinical trials and is suggested as an aid to compliance in patients who regularly eat three meals daily. A lower dose may be effective in some patients. A missed dose should be taken as soon as possible. However, if it is almost time for the next dose, the missed dose should be skipped, and then the regular dosing schedule should be resumed. Doses should not be doubled up. For patients with moderate renal impairment (creatinine clearance of 30 to 50 mL minute), a starting dosage of one 333-mg tablet taken three times daily is recommended. People with severe renal insufficiency should not take acamprosate.

29.16 Dopamine Receptor Agonists and Precursors

Dopamine agonists activate dopamine receptors in the absence of endogenous dopamine and have been widely used to treat idiopathic Parkinson’s disease, hyperprolactinemia, and certain pituitary tumors (prolactinoma). Because dopamine stimulates the heart and increases blood flow to the liver, kidneys, and other organs, low levels of dopamine are associated with low blood pressure and low cardiac input. Dopamine agonist drugs are also administered to treat shock and congestive heart failure.

Their use in psychiatry has been limited to treat such adverse effects of antipsychotic drugs as parkinsonism, extrapyramidal symptoms, akinesia, focal perioral tremors, hyperprolactinemia, galactorrhea, and neuroleptic malignant syndrome. The drugs in this class most commonly prescribed are bromocriptine (Parlodel), levodopa (also called l-Dopa; Larodopa), carbidopa-levodopa (Sinemet), and amantadine (Symmetrel). Amantadine is used primarily for the treatment of medication-induced movement disorders, such as neuroleptic-induced parkinsonism. It is also used as an antiviral agent for the prophylaxis and treatment of influenza A infection and Cotard’s syndrome, a rare neuropsychiatric disorder in which a person holds a delusional belief that he or she is dead. There are also a few reports of amantadine’s role in augmenting antidepressant medications in patients with treatment-resistant depression.

New dopamine receptor agonists include ropinirole (Requip), pramipexole (Mirapex), apomorphine (Apokyn), and pergolide (Permax). Of these drugs, pramipexole is the most widely prescribed in psychiatry as an augmenter of antidepressants. In 2007, pergolide was removed from the market because of the risk of serious damage to patients’ heart valves. In 2012, the U.S. Food and Drug Administration (FDA) notified health care professionals about a possible increased risk of heart failure with pramipexole. This warning was based on studies that suggested a potential risk of heart failure; however, further review is required because of study limitations.

PHARMACOLOGICAL ACTIONS
i-Dopa is rapidly absorbed after oral administration, and peak plasma levels are reached after 30 to 120 minutes. The half-life of i-Dopa is 90 minutes. Absorption of i-Dopa can be significantly reduced by changes in gastric pH and by ingestion with meals. Bromocriptine and ropinirole are rapidly absorbed but undergo first-pass metabolism such that only about 30 to 55 percent of the dose is bioavailable. Peak concentrations are achieved 1.5 to 3 hours after oral administration. The half-life of ropinirole is 6 hours. Pramipexole is rapidly absorbed with little first-pass metabolism and reaches peak concentrations in 2 hours. Its half-life is 8 hours. Oral forms of apomorphine have been studied, but this form is not available in the United States. Subcutaneous apomorphine injection results in rapid and controlled systemic delivery, with linear pharmacokinetics over a dose ranging from 2 to 8 mg.

After i-Dopa enters the dopaminergic neurons of the central nervous system (CNS), it is converted into the neurotransmitter dopamine. Apomorphine, bromocriptine, ropinirole, and pramipexole act directly on dopamine receptors. i-Dopa, pramipexole, and ropinirole bind about 20 times more selectively to dopamine D<sub>3</sub> than D<sub>2</sub> receptors; the corresponding ratio for bromocriptine is less than 2 to 1. Apomorphine binds selectively to D<sub>1</sub> and D<sub>2</sub> receptors, with little affinity for D<sub>3</sub> and D<sub>4</sub> receptors. i-Dopa, pramipexole, and ropinirole have no significant activity at nondopaminergic receptors, but bromocriptine binds to serotonin 5-HT<sub>1</sub> and 5-HT<sub>2</sub> and α<sub>1</sub>, α<sub>2</sub>, and β-adrenergic receptors.

**THERAPEUTIC INDICATIONS**

**Medication-induced Movement Disorders**

In present-day clinical psychiatry, dopamine receptor agonists are used for the treatment of medication-induced parkinsonism, extrapyramidal symptoms, akinesia, and focal perioral tremors. Their use has diminished sharply, however, because the incidence of medication-induced movement disorders is much lower with the use of the newer, atypical antipsychotics (serotonin-dopamine antagonists). Dopamine receptor agonists are effective in treating idiopathic restless legs syndrome and may also be helpful when this is a medication side effect. Ropinirole has an indication for restless legs syndrome.

For the treatment of medication-induced movement disorders, most clinicians rely on anticholinergics, amantadine, and antihistamines because they are equally effective and have few adverse effects. Bromocriptine remains in use in the treatment of neuroleptic malignant syndrome; however, the incidence of this disorder is diminishing with the decreased use of dopamine receptor antagonist (DRAs).

Dopamine receptor agonists are also used to counteract the hyperprolactinemic effects of DRAs, which result in the side effects of amenorrhea and galactorrhea.

**Mood Disorders**
Bromocriptine has long been used to enhance response to antidepressant drugs in refractory patients. Ropinirole has been reported to be useful as augmentation to antidepressant therapy and as a treatment for medication-resistant bipolar II depression. Ropinirole may also be helpful in the treatment of antidepressant-induced sexual dysfunction. Pramipexole is often used in the augmentation of antidepressants in treatment-resistant depression. Some studies have found pramipexole to be superior to sertraline (Zoloft) in the treatment of depression in Parkinson’s disease, as well as reducing anhedonia in Parkinson's patients.

**Sexual Dysfunction**

Dopamine receptor agonists improve erectile dysfunction in some patients. However, they are rarely used because they frequently cause adverse effects at therapeutic dosages. Phosphodiesterase-5 inhibitor agents are better tolerated and more effective (see Section 29.26).

**PRECAUTIONS AND ADVERSE REACTIONS**

Adverse effects are common with dopamine receptor agonists, thus limiting the usefulness of these drugs. Adverse effects are dosage dependent and include nausea, vomiting, orthostatic hypotension, headache, dizziness, and cardiac arrhythmias. To reduce the risk of orthostatic hypotension, the initial dosage of all dopamine receptor agonists should be quite low, with incremental increases at intervals of at least 1 week. These drugs should be used with caution in persons with hypertension, cardiovascular disease, and hepatic disease. After long-term use, persons, particularly elderly persons, may experience choreiform and dystonic movements and psychiatric disturbances—including hallucinations, delusions, confusion, depression, and mania—and other behavioral changes.

Long-term use of bromocriptine can produce retroperitoneal and pulmonary fibrosis, pleural effusions, and pleural thickening.

In general, ropinirole and pramipexole have a similar but milder adverse effect profile than L-Dopa and bromocriptine. Pramipexole and ropinirole may cause irresistible sleep attacks that occur suddenly without warning and have caused motor vehicle accidents.

The most common adverse effects of apomorphine are yawning, dizziness, nausea, vomiting, drowsiness, bradycardia, syncope, and perspiration. Hallucinations have also been reported. Apomorphine’s sedative effects are exacerbated with concurrent use of alcohol or other CNS depressants.

Dopamine receptor agonists are contraindicated during pregnancy, especially for nursing mothers, because they inhibit lactation.

**DRUG INTERACTIONS**

DRAs are capable of reversing the effects of dopamine receptor agonists, but this is not
usually clinically significant. The concurrent use of tricyclic drugs and dopamine receptor agonists has been reported to cause symptoms of neurotoxicity, such as rigidity, agitation, and tremor. They may also potentiate the hypotensive effects of diuretics and other antihypertensive medications. Dopamine receptor agonists should not be used in conjunction with monoamine oxidase inhibitors (MAOIs), including selegiline (Eldepryl), and MAOIs should be discontinued at least 2 weeks before the initiation of dopamine receptor agonist therapy.

Benzodiazepines, phenytoin (Dilantin), and pyridoxine may interfere with the therapeutic effects of dopamine receptor agonists. Ergot alkaloids and bromocriptine should not be used concurrently because they may cause hypertension and myocardial infarction. Progestins, estrogens, and oral contraceptives may interfere with the effects of bromocriptine and may raise plasma concentrations of ropinirole. Ciprofloxacin (Cipro) can raise plasma concentrations of ropinirole, and cimetidine (Tagamet) can raise plasma concentrations of pramipexole.

LABORATORY INTERFERENCES

l-Dopa administration has been associated with false reports of elevated serum and urinary uric acid concentrations, urinary glucose test results, urinary ketone test results, and urinary catecholamine concentrations. No laboratory interferences have been associated with the administration of the other dopamine receptor agonists.

DOSAGE AND CLINICAL GUIDELINES

Table 29.16-1 lists the various dopamine receptor agonists and their formulations. For the treatment of antipsychotic-induced parkinsonism, the clinician should start with a 100-mg dose of levodopa three times a day, which may be increased until the person is functionally improved. The maximum dosage of l-Dopa is 2,000 mg a day, but most persons respond to dosages below 1,000 mg per day. The dosage of the carbidopa component of the l-Dopa-carbidopa formulation should total at least 75 mg a day.
The dosage of bromocriptine for mental disorders is uncertain, although it seems prudent to begin with low dosages (1.25 mg twice daily) and to increase the dosage gradually. Bromocriptine is usually taken with meals to help reduce the likelihood of nausea.

The starting dosage of pramipexole is 0.125 mg three times daily, which is increased to 0.25 mg three times daily in the second week and is increased by 0.25 mg per dose each week until therapeutic benefit or adverse effects emerge. Persons with idiopathic Parkinson’s disease usually experience benefit at total daily doses of 1.5 mg, and the maximum daily dose is 4.5 mg.

For ropinirole, the starting dosage is 0.25 mg three times daily and is increased by 0.25 mg per dose each week to a total daily dose of 3 mg, then by 0.5 mg per dose each week to a total daily dose of 9 mg, and then by 1 mg per dose each week to a maximum dosage of 24 mg a day until therapeutic benefit or adverse effects emerge. The average daily dose for persons with idiopathic Parkinson’s disease is about 16 mg.

The recommended subcutaneous dose of apomorphine in Parkinson’s disease is 0.2 to 0.6 mL subcutaneously during acute hypomobility episodes delivered via metered injector pen. Apomorphine can be administered three times daily, with a maximum dose of 0.6 mL five times daily.

**AMANTADINE**

Amantadine is an antiviral drug used for the prophylaxis and treatment of influenza. It was found to have antiparkinsonian properties and is now used to treat that disorder as well as akinesias and other extrapyramidal signs, including focal perioral tremors (rabbit syndrome).

**Pharmacologic Actions**

Amantadine is well absorbed from the GI tract after oral administration, reaches peak plasma concentrations in approximately 2 to 3 hours, has a half-life of about 12 to 18 hours, and attains steady-state concentrations after approximately 4 to 5 days of therapy. Amantadine is excreted unmetabolized in the urine. Amantadine plasma
concentrations can be twice as high in elderly persons as in younger adults. Patients with renal failure accumulate amantadine in their bodies.

Amantadine augments dopaminergic neurotransmission in the CNS; however, the precise mechanism for the effect is unknown. The mechanism may involve dopamine release from presynaptic vesicles, blocking reuptake of dopamine into presynaptic nerve terminals, or an agonist effect on postsynaptic dopamine receptors.

Therapeutic Indications
The primary indication for amantadine use in psychiatry is to treat extrapyramidal signs and symptoms, such as parkinsonism, akinesia, and rabbit syndrome (focal perioral tremor of the choreoathetoid type) caused by the administration of DRA or SDA drugs. Amantadine is as effective as the anticholinergics (e.g., benztropine [Cogentin]) for these indications and results in improvement in approximately half of all persons who take it. Amantadine, however, is not generally considered as effective as the anticholinergics for the treatment of acute dystonic reactions and is not effective in treating tardive dyskinesia and akathisia.

Amantadine is a reasonable compromise for persons with extrapyramidal symptoms who would be sensitive to additional anticholinergic effects, particularly those taking a low-potency DRA or the elderly. Elderly persons are susceptible to anticholinergic adverse effects, both in the CNS, such as anticholinergic delirium, and in the peripheral nervous system, such as urinary retention. Amantadine is associated with less memory impairment than are the anticholinergics.

Amantadine has been reported to be of benefit in treating some selective serotonin reuptake inhibitor–associated side effects, such as lethargy, fatigue, anorgasmia, and ejaculatory inhibition.

Amantadine is used in general medical practice for the treatment of parkinsonism of all causes, including idiopathic parkinsonism.

Precautions and Adverse Effects
The most common CNS effects of amantadine are mild dizziness, insomnia, and impaired concentration (dosage related), which occur in 5 to 10 percent of all persons. Irritability, depression, anxiety, dysarthria, and ataxia occur in 1 to 5 percent of all persons. More severe CNS adverse effects, including seizures and psychotic symptoms, have been reported. Nausea is the most common peripheral adverse effect of amantadine. Headache, loss of appetite, and blotchy spots on the skin have also been reported.

Livedo reticularis of the legs (a purple discoloration of the skin caused by dilation of blood vessels) has been reported in up to 5 percent of persons who take the drug for longer than 1 month. It usually diminishes with elevation of the legs and resolves in almost all cases when drug use is terminated.

Amantadine is relatively contraindicated in persons with renal disease or a seizure disorder. Amantadine should be used with caution in persons with edema or
cardiovascular disease. Some evidence indicates that amantadine is teratogenic and therefore should not be taken by pregnant women. Because amantadine is excreted in breast milk, women who are breast-feeding should not take the drug.

Suicide attempts with amantadine overdosages are life-threatening. Symptoms can include toxic psychoses (confusion, hallucinations, aggressiveness) and cardiopulmonary arrest. Emergency treatment beginning with gastric lavage is indicated.

Drug Interactions

Coadministration of amantadine with phenelzine (Nardil) or other MAOIs can result in a significant increase in resting blood pressure. The coadministration of amantadine with CNS stimulants can result in insomnia, irritability, nervousness, and possibly seizures or irregular heartbeat. Amantadine should not be coadministered with anticholinergics because unwanted side effects—such as confusion, hallucinations, nightmares, dry mouth, and blurred vision—may be exacerbated.

Dosage and Clinical Guidelines

Amantadine is available in 100-mg capsules and as a 50-mg per 5-mL syrup. The usual starting dosage of amantadine is 100 mg given orally twice a day, although the dosage can be cautiously increased up to 200 mg given orally twice a day if indicated. Amantadine should be used in persons with renal impairment only in consultation with the physician treating the renal condition. If amantadine is successful in the treatment of the drug-induced extrapyramidal symptoms, it should be continued for 4 to 6 weeks and then discontinued to see whether the person has become tolerant to the neurological adverse effects of the antipsychotic medication. Amantadine should be tapered over 1 to 2 weeks after a decision has been made to discontinue the drug. Persons taking amantadine should not drink alcoholic beverages.

REFERENCES

Papanastasiou E, Stone JM, Shergill S. When the drugs don’t work: the potential of glutamatergic antipsychotics in...
The dopamine receptor antagonists (DRAs) represent the first group of effective agents for schizophrenia and other psychotic illnesses. The first of these drugs, the phenothiazine chlorpromazine (Thorazine), was introduced in the early 1950s. Other DRAs include all of the antipsychotics in the following groups: phenothiazines, butyrophenones, thioxanthenes, dibenzoxazepines, dihydroindoles, and diphenylbutylpiperidines. Because these agents are associated with extrapyramidal syndromes (EPSs) at clinically effective dosages, newer antipsychotic drugs—the serotonin–dopamine antagonists (SDAs)—have gradually replaced the older agents in the United States. The SDAs are differentiated from earlier drugs by their lower liability to cause extrapyramidal side effects. These newer drugs have other liabilities, most notably a propensity to cause weight gain, lipid elevations, and diabetes. Therefore, a reason to still consider use of the DRAs is their lower risk of causing significant metabolic abnormalities. Intermediate-potency DRAs, such as perphenazine (Trilafon), have been shown to be as effective and well tolerated as the SDAs. Manufacturing of molindone (Moban), the DRA with the lowest risk of weight gain and metabolic side effects, was discontinued in the United States.

PHARMACOLOGICAL ACTIONS

All of the DRAs are well absorbed after oral administration, with liquid preparations being absorbed more efficiently than tablets or capsules. Peak plasma concentrations are usually reached 1 to 4 hours after oral administration and 30 to 60 minutes after parenteral administration. Smoking, coffee, antacids, and food interfere with absorption of these drugs. Steady-state levels are reached in approximately 3 to 5 days. The half-lives of these drugs are approximately 24 hours. All can be given in one daily oral dose, if tolerated, after the patient is in a stable condition. Most DRAs are highly protein bound. Parenteral formulation of the DRAs results in a more rapid and more reliable onset of action. Bioavailability is also up to tenfold higher with parenteral administration. Most DRAs are metabolized by cytochrome P450 (CYP) CYP2D6 and 3A isozymes. However, there are differences among the specific agents.

Long-acting depot parenteral formulations of haloperidol (Haldol, Decanoate) and fluphenazine are available in the United States. These agents are usually administered once every 1 to 4 weeks, depending on the dose and the patient. It can take up to 6 months of treatment with depot formulations to reach steady-state plasma levels,
indicating that oral therapy should be continued during the first month or so of depot antipsychotic treatment.

Antipsychotic activity derives from inhibition of dopaminergic neurotransmission. The DRAs are effective when approximately 72% of dopamine $D_2$ receptors in the brain are occupied. The DRAs also block noradrenergic, cholinergic, and histaminergic receptors, with different drugs having different effects on these receptor systems.

Some generalizations can be made about the DRAs based on their potency. Potency refers to the amount of drug that is required to achieve therapeutic effects. Low-potency drugs such as chlorpromazine and thioridazine (Mellaril), given in doses of several 100 mg per day, typically produce more weight gain and sedation than high-potency agents such as haloperidol and fluphenazine, usually given in doses of less than 10 mg per day. High-potency agents are also more likely to cause EPS. Some factors influencing the pharmacological actions of DRAs are listed in Table 29.17-1.

**Table 29.17-1**
Factors Influencing the Pharmacokinetics of Antipsychotics

| Age | Elderly patients may demonstrate reduced clearance rates. |
| Medical condition | Decreased hepatic blood flow can reduce clearance. |
| Enzyme inducers | Hepatic disease can decrease clearance. |
| Carbamazepine, phenytoin, ethambutol, barbiturates. |
| Clearance inhibitors | Include SSRIs, TCAs, cimetidine, $\beta$-blockers, isoniazid, methylphenidate, erythromycin, triazolobenzodiazepines, ciprofloxacin, and ketoconazole. |
| Changes in binding protein | Hypoalbuminemia can occur with malnutrition or hepatic failure. |

**THERAPEUTIC INDICATIONS**

Many types of psychiatric and neurological disorders may benefit from treatment with DRAs. Some of these indications are shown in Table 29.17-2.

**Table 29.17-2**
Indications for Dopamine Receptor Antagonists
Schizophrenia and Schizoaffective Disorder

The DRAs are effective in both the short-term and long-term management of schizophrenia and schizoaffective disorder. They both reduce acute symptoms and prevent future exacerbations. These agents produce their most dramatic effects against the positive symptoms of schizophrenia (e.g., hallucinations, delusions, and agitation). Negative symptoms (e.g., emotional withdrawal and ambivalence) are less likely to improve significantly, and they may appear to worsen, because these drugs produce constriction of facial expression and akinesia, side effects that mimic negative symptoms.

Schizophrenia and schizoaffective disorder are characterized by remission and relapse. DRAs decrease the risk of reemergence of psychosis in patients who have recovered while on medication. After a first episode of psychosis, patients should be maintained on medication for 1 to 2 years; after multiple episodes, for 2 to 5 years.

Mania

DRAs are effective for treating psychotic symptoms of acute mania. Because antimanic agents (e.g., lithium) generally have a slower onset of action than do antipsychotics in the treatment of acute symptoms, it is standard practice to initially combine either a DRA or an SDA with lithium (Eskalith), divalproex (Depakote), lamotrigine (Lamictal), or carbamazepine (Tegretol) and then to gradually withdraw the antipsychotic.

Depression with Psychotic Symptoms

Combination treatment with an antipsychotic and an antidepressant is one of the treatments of choice for major depressive disorder with psychotic features; the other is electroconvulsive therapy (ECT).

Delusional Disorder

Patients with delusional disorder often respond favorably to treatment with these drugs. Some persons with borderline personality disorder who may develop paranoid thinking
Severe Agitation and Violent Behavior

Severely agitated and violent patients, regardless of diagnosis, may be treated with DRAs. Symptoms such as extreme irritability, lack of impulse control, severe hostility, gross hyperactivity, and agitation respond to short-term treatment with these drugs. Children with mental disabilities, especially those with profound mental retardation and autistic disorder, often have associated episodes of violence, aggression, and agitation that respond to treatment with antipsychotic drugs; however, the repeated administration of antipsychotics to control disruptive behavior in children is controversial.

Tourette’s Disorder

DRAs are used to treat Tourette’s disorder, a neurobehavioral disorder marked by motor and vocal tics. Haloperidol and pimozide (Orap) are the drugs most frequently used, but other DRAs are also effective. Some clinicians prefer to use clonidine (Catapres) for this disorder because of its lower risk of neurological side effects.

Borderline Personality Disorder

Patients with borderline personality disorder who experience transient psychotic symptoms, such as perceptual disturbances, suspiciousness, ideas of reference, and aggression, may need to be treated with a DRA. This disorder is also associated with mood instability, so patients should be evaluated for possible treatment with mood-stabilizing agents.

Dementia and Delirium

About two thirds of agitated, elderly patients with various forms of dementia improve when given a DRA. Low doses of high-potency drugs (e.g., 0.5 to 1 mg a day of haloperidol) are recommended. DRAs are also used to treat psychotic symptoms and agitation associated with delirium. The cause of the delirium needs to be determined because toxic deliriums caused by anticholinergic agents can be exacerbated by low-potency DRAs, which often have significant antimuscarinic activity. Orthostasis, parkinsonism, and worsened cognition are the most problematic side effects in this elderly population.

Substance-induced Psychotic Disorder

Intoxication with cocaine, amphetamines, alcohol, phencyclidine, or other drugs can cause psychotic symptoms. Because these symptoms tend to be time limited, it is preferable to avoid use of a DRA unless the patient is severely agitated and aggressive. Usually, benzodiazepines can be used to calm the patient. Benzodiazepines should be
used instead of DRAs in cases of phencyclidine intoxication. When a patient is experiencing hallucinations or delusions as a result of alcohol withdrawal, DRAs may increase the risk of seizure.

**Childhood Schizophrenia**

Children with schizophrenia benefit from treatment with antipsychotic medication, although considerably less research has been devoted to this population. Studies are currently under way to determine if intervention with medication at the very earliest signs of disturbance in children genetically at risk for schizophrenia can prevent the emergence of more florid symptoms. Careful consideration needs to be given to side effects, especially those involving cognition and alertness.

**Other Psychiatric and Nonpsychiatric Indications**

The DRAs reduce the chorea in the early stages of Huntington’s disease. Patients with this disease may develop hallucinations, delusions, mania, or hypomania. These and other psychiatric symptoms respond to DRAs. High-potency DRAs should be used. However, clinicians should be aware that patients with the rigid form of this disorder may experience acute EPS. The use of DRAs to treat impulse control disorders should be reserved for patients in whom other interventions have failed. Patients with pervasive developmental disorder may exhibit hyperactivity, screaming, and agitation with combativeness. Some of these symptoms respond to high-potency DRAs, but there is little research evidence supporting benefits in these patients.

The rare neurological disorders ballismus and hemiballismus (which affect only one side of the body), characterized by propulsive movements of the limbs away from the body, also respond to treatment with antipsychotic agents. Other miscellaneous indications for the use of DRAs include the treatment of nausea, emesis, intractable hiccups, and pruritus. Endocrine disorders and temporal lobe epilepsy may be associated with psychosis that responds to antipsychotic treatment.

The most common side effects of DRAs are neurological. As a rule, low-potency drugs cause most nonneurological adverse effects, and the high-potency drugs cause most neurological adverse effects.

**PRECAUTIONS AND ADVERSE REACTIONS**

Table 29.17-3 summarizes the most common adverse events associated with the use of DRAs.

Neuroleptic Malignant Syndrome

A potentially fatal side effect of DRA treatment, neuroleptic malignant syndrome, can occur at any time during the course of DRA treatment. Symptoms include extreme hyperthermia, severe muscular rigidity and dystonia, akinesia, mutism, confusion, agitation, and increased pulse rate and blood pressure. Laboratory findings include increased white blood cell (WBC) count, and levels of creatinine phosphokinase, liver enzymes, plasma myoglobin, and myoglobinuria, occasionally associated with renal failure. The symptoms usually evolve over 24 to 72 hours, and the untreated syndrome lasts 10 to 14 days. The diagnosis is often missed in the early stages, and the withdrawal or agitation may mistakenly be considered to reflect increased psychosis. Men are affected more frequently than are women, and young persons are affected more commonly than are elderly persons. The mortality rate can reach 20 to 30 percent, or even higher when depot medications are involved. Rates are also increased when high doses of high-potency agents are used.

If neuroleptic malignant syndrome is suspected, the DRA should be stopped immediately and the following done: medical support to cool the person; monitoring of vital signs, electrolytes, fluid balance, and renal output; and symptomatic treatment of fever. Antiparkinsonian medications may reduce some of the muscle rigidity. Dantrolene (Dantrium), a skeletal muscle relaxant (0.8 to 2.5 mg/kg every 6 hours, up to a total dosage of 10 mg a day) may be useful in the treatment of this disorder. When the person can take oral medications, dantrolene can be given in doses of 100 to 200 mg a day. Bromocriptine (20 to 30 mg a day in four divided doses) or amantadine can be added to the regimen. Treatment should usually be continued for 5 to 10 days. When drug treatment is restarted, the clinician should consider switching to a low-potency drug or an SDA, although these agents—including clozapine—may also cause neuroleptic malignant syndrome.

*a* Anti-α-adrenergic and anticholinergic effects.

*b* Excluding tardive dyskinesia, which appears to be produced to the same degree and frequency by all agents with equipotent antipsychotic dosages.

*c* Pimozide is used principally in the treatment of Tourette’s disorder; prochlorperazine is used rarely, if ever, as an antipsychotic agent.

Seizure Threshold
DRAs may lower the seizure threshold. Chlorpromazine, thioridazine, and other low-potency drugs are thought to be more epileptogenic than are high-potency drugs. The risk of inducing a seizure by drug administration warrants consideration when the person already has a seizure disorder or brain lesion.

Sedation
Blockade of histamine H\textsubscript{1} receptors is the usual cause of sedation associated with DRAs. Chlorpromazine is the most sedating typical antipsychotic. The relative sedative properties of the drugs are summarized in Table 29.17-3. Giving the entire daily dose at bedtime usually eliminates any problems from sedation, and tolerance for this adverse effect often develops.

Central Anticholinergic Effects
The symptoms of central anticholinergic activity include severe agitation; disorientation to time, person, and place; hallucinations; seizures; high fever; and dilated pupils. Stupor and coma may ensue. The treatment of anticholinergic toxicity consists of discontinuing the causal agent or agents, close medical supervision, and physostigmine (Antilirium, Eserine), 2 mg by slow intravenous (IV) infusion, repeated within 1 hour as necessary. Too much physostigmine is dangerous, and symptoms of physostigmine toxicity include hypersalivation and sweating. Atropine sulfate (0.5 mg) can reverse the effects of physostigmine toxicity.

Cardiac Effects
The DRAs decrease cardiac contractility, disrupt enzyme contractility in cardiac cells, increase circulating levels of catecholamines, and prolong atrial and ventricular conduction time and refractory periods. Low-potency DRAs, particularly the phenothiazines, are usually more cardiotoxic than are high-potency drugs. One exception is haloperidol, which has been linked to abnormal heart rhythm, ventricular arrhythmias, torsades de pointes, and sudden death when injected IV. Pimozide, sulpiride, and droperidol (a butyrophenone) also prolong the QTc interval and have clearly been associated with torsades de pointes and sudden death. In one study, thioridazine was responsible for 28 (61 percent) of the 46 sudden antipsychotic deaths. In 15 of these cases, it was the only drug ingested. Chlorpromazine also causes prolongation of the QT and PR intervals, blunting of the T waves, and depression of the ST segment. These drugs are thus indicated only when other agents have been ineffective.

Sudden Death
Occasional reports of sudden cardiac death during treatment with DRAs may be the
result of cardiac arrhythmias. Other causes may include seizure, asphyxiation, malignant hyperthermia, heat stroke, and neuroleptic malignant syndrome. However, there does not appear to be an overall increase in the incidence of sudden death linked to the use of antipsychotics.

Orthostatic (Postural) Hypotension

Orthostatic (postural) hypotension is most common with low-potency drugs, particularly chlorpromazine, thioridazine, and chlorprothixene. When using intramuscular (IM) low-potency DRAs, the clinician should measure the patient’s blood pressure (lying and standing) before and after the first dose and during the first few days of treatment.

Orthostatic hypotension is mediated by adrenergic blockade and occurs most frequently during the first few days of treatment. Tolerance often develops for this side effect, which is why initial dosing of these drugs is lower than the usual therapeutic dose. Fainting or falls, although uncommon, may lead to injury. Patients should be warned of this side effect and instructed to rise slowly after sitting and reclining. Patients should avoid all caffeine and alcohol; should drink at least 2 L of fluid a day; and if not under treatment for hypertension, should add liberal amounts of salt to their diet. Support hose may help some persons.

Hypotension can usually be managed by having patients lie down with their feet higher than their heads and pump their legs as if bicycling. Volume expansion or vasopressor agents, such as norepinephrine (Levophed), may be indicated in severe cases. Because hypotension is produced by α-adrenergic blockade, the drugs also block the α-adrenergic stimulating properties of epinephrine, leaving the β-adrenergic stimulating effects untouched. Therefore, the administration of epinephrine results in a paradoxical worsening of hypotension and is contraindicated in cases of antipsychotic-induced hypotension. Pure α-adrenergic pressor agents, such as metaraminol (Aramine) and norepinephrine, are the drugs of choice in the treatment of the disorder.

Hematologic Effects

Temporary leukopenia with a WBC count of about 3,500 is a common but not serious problem. Agranulocytosis, a life-threatening hematologic problem, occurs in about 1 in 10,000 persons treated with DRAs. Thrombocytopenic or nonthrombocytopenic purpura, hemolytic anemias, and pancytopenia may occur rarely in persons treated with DRAs. Although routine complete blood counts (CBCs) are not indicated, if a person reports a sore throat and fever, a CBC should be done immediately to check for the possibility of a serious blood dyscrasia. If blood index values are low, administration of DRAs should be stopped, and the patient should be transferred to a medical facility. The mortality rate for the complication may be as high as 30 percent.

Peripheral Anticholinergic Effects

Peripheral anticholinergic effects, consisting of dry mouth and nose, blurred vision,
constipation, urinary retention, and mydriasis, are common, especially with low-potency DRAs, for example, chlorpromazine, thioridazine, mesoridazine (Serentil). Some persons may also have nausea and vomiting.

Constipation should be treated with the usual laxative preparations, but severe constipation can progress to paralytic ileus. A decrease in the DRA dosage is warranted in such cases. Pilocarpine (Salagen) may be used to treat paralytic ileus, although the relief is only transitory. Bethanechol (Urecholine) (20 to 40 mg a day) may be useful in some persons with urinary retention.

Weight gain is associated with increased mortality and morbidity and with medication noncompliance. Low-potency DRAs may cause significant weight gain but not as much as is seen with the SDAs olanzapine (Zyprexa) and clozapine (Clozaril). Molindone and perhaps loxapine (Loxitane) appear to be least likely to cause weight gain.

**Endocrine Effects**

Blockade of the dopamine receptors in the tuberoinfundibular tract results in the increased secretion of prolactin, which can result in breast enlargement, galactorrhea, amenorrhea, and inhibited orgasm in women and impotence in men. The SDAs, with the exception of risperidone (Risperdal), are not particularly associated with an increase in prolactin levels and may be the drugs of choice for persons experiencing disturbing side effects from increased prolactin release.

**Sexual Adverse Effects**

Both men and women taking DRAs can experience anorgasmia and decreased libido. Up to 50 percent of men who take antipsychotics report ejaculatory and erectile disturbances. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) are often used to treat psychotropic-induced orgasmic dysfunction, but they have not been studied in combination with the DRAs. Thioridazine is particularly associated with decreased libido and retrograde ejaculation in men. Priapism and reports of painful orgasms have also been described, both possibly resulting from α₁-adrenergic antagonist activity.

**Skin and Eye Effects**

Allergic dermatitis and photosensitivity may occur, especially with low-potency agents. Urticarial, maculopapular, petechial, and edematous eruptions may occur early in treatment, generally in the first few weeks, and remit spontaneously. A photosensitivity reaction that resembles a severe sunburn also occurs in some persons taking chlorpromazine. Persons should be warned of this adverse effect, should spend no more than 30 to 60 minutes in the sun, and should use sunscreens. Long-term chlorpromazine use is associated with blue-gray discoloration of skin areas exposed to sunlight. The skin changes often begin with a tan or golden brown color and progress to such colors as slate gray, metallic blue, and purple. These discolorations resolve when the patient is switched to another medication.
Irreversible retinal pigmentation is associated with the use of thioridazine at dosages above 1,000 mg a day. An early symptom of the side effect can sometimes be nocturnal confusion related to difficulty with night vision. The pigmentation can progress even after thioridazine administration is stopped, finally resulting in blindness. It is for this reason that the maximum recommended dosage of thioridazine is 800 mg per day.

Patients taking chlorpromazine may develop a relatively benign pigmentation of the eyes, characterized by whitish brown granular deposits concentrated in the anterior lens and posterior cornea and visible only by slit-lens examination. The deposits can progress to opaque white and yellow-brown granules, often stellate. Occasionally, the conjunctiva is discolored by a brown pigment. No retinal damage is seen, and vision is almost never impaired. This condition gradually resolves when chlorpromazine is discontinued.

Jaundice

Elevations of liver enzymes during treatment with a DRA tend to be transient and not clinically significant. When chlorpromazine first came into use, cases of obstructive or cholestatic jaundice were reported, usually in the first month of treatment and heralded by symptoms of upper abdominal pain, nausea, and vomiting. This was followed by fever; rash; eosinophilia; bilirubin in the urine; and increases in levels of serum bilirubin, alkaline phosphatase, and hepatic transaminases. Reported cases are now extremely rare, but if jaundice occurs, the medication should be discontinued.

Overdoses

Overdoses typically consist of exaggerated DRA side effects. Symptoms and signs include central nervous system (CNS) depression, EPS, mydriasis, rigidity, restlessness, decreased deep tendon reflexes, tachycardia, and hypotension. The severe symptoms of overdose include delirium, coma, respiratory depression, and seizures. Haloperidol may be among the safest typical antipsychotics in overdose. After an overdose, electroencephalography (EEG) shows diffuse slowing and low voltage. Extreme overdose may lead to delirium and coma, with respiratory depression and hypotension. Life-threatening overdose usually involves ingestion of other CNS depressants, such as alcohol or benzodiazepines.

Activated charcoal, if possible, and gastric lavage should be administered if the overdose is recent. Emetics are not indicated because the antiemetic actions of the DRAs inhibit their efficacy. Seizures can be treated with IV diazepam (Valium) or phenytoin (Dilantin). Hypotension can be treated with either norepinephrine or dopamine but not epinephrine.

Pregnancy and Lactation

There is a low correlation between the use of antipsychotics during pregnancy and congenital malformations. Nevertheless, antipsychotics should be avoided during
pregnancy, particularly in the first trimester unless the benefit outweighs the risk. High-potency drugs are preferable to low-potency drugs because the low-potency drugs are associated with hypotension.

DRAs are secreted in the breast milk, although concentrations are low. Women taking these agents should be advised against breastfeeding.

**DRUG INTERACTIONS**

Many pharmacokinetic and pharmacodynamic drug interactions are associated with these drugs (Table 29.17-4). CYP2D6 is the most common hepatic isozyme involved in DRA pharmacokinetic interactions. Other common drug interactions affect the absorption of the DRAs.

<table>
<thead>
<tr>
<th>Table 29.17-4</th>
</tr>
</thead>
<tbody>
<tr>
<td>Antipsychotic Drug Interactions</td>
</tr>
</tbody>
</table>
Antacids, activated charcoal, cholestyramine (Questran), kaolin, pectin, and cimetidine (Tagamet) taken within 2 hours of antipsychotic administration can reduce the absorption of these drugs. Anticholinergics may decrease the absorption of the DRAs. The additive anticholinergic activity of the DRAs, anticholinergics, and tricyclic drugs may result in anticholinergic toxicity. Digoxin (Lanoxin) and steroids, both of which decrease gastric motility, can increase DRA absorption.

Phenothiazines, especially thioridazine, may decrease the metabolism of and cause toxic concentrations of phenytoin. Barbiturates may increase the metabolism of DRAs.

Tricyclic drugs and selective serotonin reuptake inhibitors (SSRIs) that inhibit CYP2D6—paroxetine (Paxil), fluoxetine (Prozac), and fluvoxamine (Luvox)—interact with
DRAs, resulting in increased plasma concentrations of both drugs. The anticholinergic, sedative, and hypotensive effects of the drugs may also be additive.

Typical antipsychotics may inhibit the hypotensive effects of α-methyldopa (Aldomet). Conversely, typical antipsychotics may have an additive effect on some hypotensive drugs. Antipsychotic drugs have a variable effect on the hypotensive effects of clonidine. Propranolol (Inderal) coadministration increases the blood concentrations of both drugs.

The DRAs potentiate the CNS-depressant effects of the sedatives, antihistamines, opiates, opioids, and alcohol, particularly in persons with impaired respiratory status. When these agents are taken with alcohol, the risk for heat stroke may be increased.

Cigarette smoking may decrease the plasma levels of the typical antipsychotic drugs. Epinephrine has a paradoxical hypotensive effect in persons taking typical antipsychotics. These drugs may decrease the blood concentration of warfarin (Coumadin), resulting in decreased bleeding time. The phenothiazines, thioridazine, and pimozide should not be coadministered with other agents that prolong the QT interval. Thioridazine is contraindicated in patients taking drugs that inhibit the CYP2D6 isoenzyme or in patients with reduced levels of CYP2D6.

LABORATORY INTERFERENCES
Chlorpromazine and perphenazine (Trilafon) may cause both false-positive and false-negative results in immunological pregnancy tests and falsely elevated bilirubin (with reagent test strips) and urobilinogen (with Ehrlich’s reagent test) values. These drugs have also been associated with an abnormal shift in results of the glucose tolerance test, although that shift may reflect the effects of the drugs on the glucose-regulating system. Phenothiazines have been reported to interfere with the measurement of 17-ketosteroids and 17-hydroxycorticosteroids and to produce false-positive results in tests for phenylketonuria.

DOSAGE AND CLINICAL GUIDELINES
Contraindications to the use of DRAs include the following: (1) a history of a serious allergic response; (2) the possible ingestion of a substance that will interact with the antipsychotic to induce CNS depression (e.g., alcohol, opioids, barbiturates, and benzodiazepines) or anticholinergic delirium (e.g., scopolamine and possibly phencyclidine [PCP]); (3) the presence of a severe cardiac abnormality; (4) a high risk for seizures; (5) the presence of narrow-angle glaucoma or prostatic hypertrophy if a drug with high anticholinergic activity is to be used; and (6) the presence or a history of tardive dyskinesia. Antipsychotics should be administered with caution in persons with hepatic disease, because impaired hepatic metabolism may result in high plasma concentrations. The usual assessment should include a CBC with WBC indexes, liver function tests, and electrocardiography (ECG), especially in women older than 40 years of age and men older than 30 years of age. Elderly persons and children are more sensitive to side effects than are young adults, so the dosage of the drug should be adjusted accordingly.
Various patients may respond to widely different dosages of antipsychotics; therefore, there is no set dosage for any given antipsychotic drug. Because of side effects, it is reasonable clinical practice to begin at a low dosage and increase as necessary. It is important to remember that the maximal effects of a particular dosage may not be evident for 4 to 6 weeks. Available preparations and dosages of the DRAs are given in Table 29.17-5.

IM, intramuscular; PO, oral.

**Short-term Treatment**

The equivalent of 5 to 20 mg of haloperidol is a reasonable dose for an adult in an acute state. An elderly person may benefit from as little as 1 mg of haloperidol. The administration of more than 25 mg of chlorpromazine in one injection may result in serious hypotension. IM administration results in peak plasma levels in about 30 minutes versus 90 minutes using the oral route. Doses of drugs for IM administration are about half those given by the oral route. In a short-term treatment setting, the person should be observed for 1 hour after the first dose of medication. After that time, most clinicians administer a second dose or a sedative agent (e.g., a benzodiazepine) to achieve effective behavioral control. Possible sedatives include lorazepam (Ativan) (2 mg IM) and amobarbital (50 to 250 mg IM).
Rapid Neuroleptization

Rapid neuroleptization (also called psychotolysis) is the practice of administering hourly IM doses of antipsychotic medications until marked sedation is achieved. However, several research studies have shown that merely waiting several more hours after one dose yields the same clinical improvement as is seen with repeated doses. Nevertheless, clinicians must be careful to keep patients from becoming violent while they are psychotic. Clinicians can help prevent violent episodes by using adjuvant sedatives or by temporarily using physical restraints until the persons can control their behavior.

Early Treatment

A full 6 weeks may be necessary to evaluate the extent of the improvement in psychotic symptoms. However, agitation and excitement usually improve quickly with antipsychotic treatment. About 75 percent of persons with a short history of illness show significant improvement in their psychosis. Psychotic symptoms, both positive and negative, usually continue to improve 3 to 12 months after the initiation of treatment.

About 5 mg of haloperidol or 300 mg of chlorpromazine is a usual effective daily dose. In the past, much higher doses were used, but evidence suggests that it resulted in more side effects without additional benefits. A single daily dose is usually given at bedtime to help induce sleep and to reduce the incidence of adverse effects. However, bedtime dosing for elderly persons may increase their risk of falling if they get out of bed during the night. The sedative effects of typical antipsychotics last only a few hours, in contrast to the antipsychotic effects, which last for 1 to 3 days.

Intermittent Medications

It is common clinical practice to order medications to be given intermittently as needed (PRN). Although this practice may be reasonable during the first few days that a person is hospitalized, the amount of time the person takes antipsychotic drugs, rather than an increase in dosage, is what produces therapeutic improvement. Clinicians on inpatient services may feel pressured by staff members to write PRN antipsychotic orders; such orders should include specific symptoms, how often the drugs should be given, and how many doses can be given each day. Clinicians may choose to use small doses for the PRN doses (e.g., 2 mg of haloperidol) or use a benzodiazepine instead (e.g., 2 mg of lorazepam IM). If PRN doses of an antipsychotic are necessary after the first week of treatment, the clinician may want to consider increasing the standing daily dose of the drug.

Maintenance Treatment

The first 3 to 6 months after a psychotic episode are usually considered a period of stabilization. After that time, the dosage of the antipsychotic can be decreased about 20 percent every 6 months until the minimum effective dosage is found. A person is usually
maintained on antipsychotic medications for 1 to 2 years after the first psychotic episode. Antipsychotic treatment is often continued for 5 years after a second psychotic episode, and lifetime maintenance is considered after the third psychotic episode, although attempts to reduce the daily dosage can be made every 6 to 12 months.

Antipsychotic drugs are effective in controlling psychotic symptoms, but persons may report that they prefer being off the drugs because they feel better without them. The clinician must discuss maintenance medication with patients and take into account their wishes, the severity of their illnesses, and the quality of their support systems. It is essential for the clinician to know enough about the patient’s life to try to predict upcoming stressors that might require increasing the dosage or closely monitoring compliance.

**Long-acting Depot Medications**

Long-acting depot preparations may be needed to overcome problems with compliance. IM preparations are typically given once every 1 to 4 weeks.

Two depot preparations, a decanoate and an enanthate, of fluphenazine and a decanoate preparation of haloperidol are available in the United States. The preparations are injected IM into an area of large muscle tissue, from which they are absorbed slowly into the blood. Decanoate preparations can be given less frequently than enanthate preparations because they are absorbed more slowly. Although stabilizing a person on the oral preparation of the specific drugs is not necessary before initiating the depot form, it is good practice to give at least one oral dose of the drug to assess the possibility of an adverse effect, such as severe EPS or an allergic reaction.

It is reasonable to begin with either 12.5 mg (0.5 mL) of fluphenazine preparation or 25 mg (0.5 mL) of haloperidol decanoate. If symptoms emerge in the next 2 to 4 weeks, the person can be treated temporarily with additional oral medications or with additional small depot injections. After 3 to 4 weeks, the depot injection can be increased to a single dose equal to the total of the doses given during the initial period.

A good reason to initiate depot treatment with low doses is that the absorption of the preparations may be faster than usual at the onset of treatment, resulting in frightening episodes of dystonia that eventually discourage compliance with the medication. Some clinicians keep persons drug free for 3 to 7 days before initiating depot treatment and give small doses of the depot preparations (3.125 mg of fluphenazine or 6.25 mg of haloperidol) every few days to avoid those initial problems.

**PLASMA CONCENTRATIONS**

Genetic differences among persons and pharmacokinetic interactions with other drugs influence the metabolism of the antipsychotics. If a person has not improved after 4 to 6 weeks of treatment, the plasma concentration of the drug should be determined if feasible. After a patient has been on a particular dosage for at least five times the half-life of the drug and thus approaches steady-state concentrations, blood levels may be helpful. It is standard practice to obtain plasma samples at trough levels—just before
the daily dose is given, usually at least 12 hours after the previous dose and most commonly 20 to 24 hours after the previous dose. In fact, most antipsychotics have no well-defined dose–response curve. The best-studied drug is haloperidol, which may have a therapeutic window ranging from 2 to 15 ng/mL. Other therapeutic ranges that have been reasonably well documented are 30 to 100 ng/mL for chlorpromazine and 0.8 to 2.4 ng/mL for perphenazine.

Treatment-resistant Persons
Unfortunately, 10 to 35 percent of persons with schizophrenia do not obtain significant benefit from the antipsychotic drugs. Treatment resistance is a failure on at least two adequate trials of antipsychotics from two pharmacological classes. It is useful to determine plasma concentrations for such persons because it is possible that they are slow or rapid metabolizers or are not taking their medication. Clozapine has been conclusively shown to be effective when given to patients who have failed multiple trials of DRAs.

Adjunctive Medications
It is common practice to use DRAs in conjunction with other psychotropic agents, either to treat side effects or to further improve symptoms. Most commonly, this involves the use of lithium or other mood-stabilizing agents, SSRIs, or benzodiazepines. It was once held that antidepressant drugs exacerbated psychosis in patients with schizophrenia. In all likelihood, this observation involved patients with bipolar disorder who were misdiagnosed as having schizophrenia. Abundant evidence suggests that antidepressants in fact improve symptoms of depression in patients with schizophrenia. In some cases, amphetamines can be added to DRAs if patients remain withdrawn and apathetic.

CHOICE OF DRUG
Given their proven efficacy in managing acute psychotic symptoms and the fact that prophylactic administration of antiparkinsonian medication prevents or minimizes acute motor abnormalities, DRAs are still valuable, especially for short-term therapy. There is a considerable cost advantage to a DRA antiparkinsonian regimen compared with monotherapy with a newer antipsychotic agent. Concern about the development of DRA-induced tardive dyskinesia is the major deterrent to long-term use of these drugs, yet it is not clear that SDAs are completely free of this complication. Thus, DRAs still occupy an important role in psychiatric treatment. DRAs are not predictably interchangeable. For reasons that cannot be explained, some patients do better on one drug than another. Choice of a particular DRA should be based on the known adverse effect profile of the drugs. Other than a significant advantage in terms of medication cost, the choice currently would be an SDA. If a DRA is thought to be preferable, a high-potency antipsychotic is favored, even though it may be associated with more neurological adverse effects, mainly because there is a higher incidence of other adverse
effects (e.g., cardiac, hypotensive, epileptogenic, sexual, and allergic) with the low-potency drugs. If sedation is a desired goal, either a low-potency antipsychotic can be given in divided doses or a benzodiazepine can be coadministered.

An unpleasant or dysphoric reaction (a subjective sense of restlessness, oversedation, and acute dystonia) to the first dose of an antipsychotic predicts future poor response and noncompliance. Prophylactic use of antiparkinsonian medications may prevent this reaction. In general, clinicians should be vigilant about serious side effects and adverse events (described above) regardless of which drug is used.

29.18 Lamotrigine

Lamotrigine (Lamictal) was developed as a result of screening folate antagonists as anticonvulsants. Lamotrigine proved effective in several animal models of epilepsy, was
developed as an antiepileptic drug, and was marketed for the adjunctive treatment of partial seizures in the United States in 1995. Initial, postmarketing, open, clinical experience suggested efficacy in a variety of neurological and psychiatric conditions, coupled with good tolerability (aside from the risk of rash). Later, double-blind, placebo-controlled studies revealed that lamotrigine was useful for some, but not all, of the neurological and psychiatric conditions reported in open studies. Therefore, lamotrigine appeared effective as maintenance treatment for bipolar disorder and was approved for maintenance treatment of bipolar I disorder in 2003. Lamotrigine also appeared to have potential utility in acute bipolar depression, but the magnitude of the effect was too modest to yield consistently superior performance compared with placebo, and hence lamotrigine did not receive approval for the treatment of acute bipolar depression. Similarly, limited data suggested lamotrigine had potential utility in rapid-cycling bipolar disorder. Lamotrigine did not appear to be effective as a main intervention in acute mania. Thus, lamotrigine has emerged as an agent that appears to “stabilize mood from below” in the sense that it may maximally impact the depressive component of bipolar disorders.

PHARMACOLOGICAL ACTIONS
Lamotrigine is completely absorbed, has a bioavailability of 98%, and has a steady-state plasma half-life of 25 hours. However, the rate of metabolism of lamotrigine varies over a sixfold range, depending on which other drugs are administered concomitantly. Dosing is escalated slowly to twice-a-day maintenance dosing. Food does not affect its absorption, and it is 55 percent protein bound in the plasma; 94% of lamotrigine and its inactive metabolites are excreted in the urine. Among the better-delineated biochemical actions of lamotrigine are blockade of voltage-sensitive sodium channels, which in turn modulates release of glutamate and aspartate, and has a slight effect on calcium channels. Lamotrigine modestly increases plasma serotonin concentrations, possibly through inhibition of serotonin reuptake, and is a weak inhibitor of serotonin 5-HT₃ receptors.

THERAPEUTIC INDICATIONS
Bipolar Disorder
Lamotrigine is indicated in the treatment of bipolar disorder and may prolong the time between episodes of depression and mania. It is more effective in lengthening the intervals between depressive episodes than manic episodes. It is also effective as treatment for rapid-cycling bipolar disorder.

Other Indications
There have been reports of therapeutic benefit in the treatment of borderline personality disorder and in the treatment for various pain syndromes.
Lamotrigine is remarkably well tolerated. The absence of sedation, weight gain, and other metabolic effects is noteworthy. The most common adverse effects—dizziness, ataxia, somnolence, headache, diplopia, blurred vision, and nausea—are typically mild. Anecdotal reports of cognitive impairment and joint or back pain are common.

The appearance of a rash, which is common and occasionally very severe, is a source of concern. About 8 percent of patients started on lamotrigine develop a benign maculopapular rash during the first 4 months of treatment, and the drug should be discontinued if a rash develops (see Color Plate 29.18-1). Even though these rashes are benign, there is concern that in some cases, they may represent early manifestations of Stevens–Johnson syndrome or toxic epidermal necrolysis. Nevertheless, even if lamotrigine is discontinued immediately upon development of rash or other signs of hypersensitivity reaction, such as fever and lymphadenopathy, this may not prevent subsequent development of a life-threatening rash or permanent disfiguration.

Estimates of the rate of serious rash vary, depending on the source of the data. In some studies, the incidence of serious rashes was 0.08 percent in adult patients receiving lamotrigine as initial monotherapy and 0.13 percent in adult patients receiving lamotrigine as adjunctive therapy. German registry data, based on clinical practice, suggest that the risk of rash may be as low as 1 in 5,000 patients. The appearance of any type of rash necessitates immediate discontinuation of drug administration.

It is known that the likelihood of a rash increases if the recommended starting dose and speed of dose increase exceed what is recommended. Concomitant administration of valproic acid also increases risk and should be avoided if possible. If valproate is used, a more conservative dosing regimen is followed. Children and adolescents younger than age 16 years appear to be more susceptible to rash with lamotrigine. If patients miss more than four consecutive days of lamotrigine treatment, they need to restart therapy at the initial starting dose and titrate upward as if they had not already been on the medication.
LABORATORY TESTING

There is no proven correlation between lamotrigine blood concentrations and either antiseizure effects or efficacy in bipolar disorders. Laboratory tests are not useful in predicting the occurrence of adverse events.

DRUG INTERACTIONS

Lamotrigine has significant, well-characterized drug interactions involving other anticonvulsants. The most potentially serious lamotrigine drug interaction involves concurrent use of valproic acid, which doubles serum lamotrigine concentrations. Lamotrigine decreases the plasma concentration of valproic acid by 25 percent. Sertraline (Zoloft) also increases plasma lamotrigine concentrations, but to a lesser extent than does valproic acid. Lamotrigine concentrations are decreased by 40 to 50 percent, with concomitant administration of carbamazepine, phenytoin, or phenobarbital. Combinations of lamotrigine and other anticonvulsants have complex effects on the time of peak plasma concentration and the plasma half-life of lamotrigine.

LABORATORY INTERFERENCES

Lamotrigine and topiramate do not interfere with any laboratory tests.

DOSAGE AND ADMINISTRATION

In the clinical trials leading to the approval of lamotrigine as a treatment for bipolar disorder, no consistent increase in efficacy was associated with doses above 200 mg per day. Most patients should take between 100 and 200 mg a day. In epilepsy, the drug is administered twice daily, but in bipolar disorder, the total dose can be taken once a day, either in the morning or night, depending on whether the patient finds the drug activating or sedating.

Lamotrigine is available as unscored 25, 100, 150, and 200 mg tablets. The major determinant of lamotrigine dosing is minimization of the risk of rash. Lamotrigine should not be taken by anyone younger than 16 years of age. Because valproic acid markedly slows the elimination of lamotrigine, concomitant administration of these two drugs necessitates a much slower titration (Table 29.18-1). People with renal insufficiency should aim for a lower maintenance dosage. Appearance of any type of rash necessitates immediate discontinuation of lamotrigine administration. Lamotrigine should usually be discontinued gradually over 2 weeks unless a rash emerges, in which case it should be discontinued over 1 to 2 days.

Lamotrigine orally disintegrating tablets (Lamictal ODT) are available for patients who have difficulty swallowing. It is the only antiepileptic treatment that is available in an orally disintegrating formulation. It is available in 25, 50, 100, and 200 mg strengths and matches the dose of lamotrigine tablets. Chewable dispersible tablets of 2, 5, and 25 mg are also available.

The effectiveness of lithium for mania and for the prophylactic treatment of manic-depressive disorder was established in the early 1950s as a result of research done by John F.J. Cade, an Australian psychiatrist. Concerns about toxicity limited initial acceptance of lithium use in the United States, but its use increased gradually in the late 1960s. It was not until 1970 that the Food and Drug Administration (FDA) approved its labeling for the treatment of mania. The only other approved FDA indication came in 1974, when it was accepted as maintenance therapy in patients with a history of mania. For several decades, lithium was the only drug approved for both acute and maintenance treatment. It is also used as an adjunctive medication in the treatment of major depressive disorder.

Lithium (Li), a monovalent ion, is a member of the group IA alkali metals on the periodic table, a group that also includes sodium, potassium, rubidium, cesium, and francium. Lithium exists in nature as both $^6\text{Li}$ (7.42%) and $^7\text{Li}$ (92.58%). The latter isotope allows the imaging of lithium by magnetic resonance spectroscopy. Some 300 mg of lithium is contained in 1,597 mg of lithium carbonate ($\text{Li}_2\text{CO}_3$). Most lithium used in the United States is obtained from dry lake mining in Chile and Argentina.

**PHARMACOLOGICAL ACTIONS**

Lithium is rapidly and completely absorbed after oral administration, with peak serum concentrations occurring in 1 to 1.5 hours with standard preparations and in 4 to 4.5 hours with slow-release and controlled-release preparations. Lithium does not bind to plasma proteins, is not metabolized, and is excreted through the kidneys. The plasma half-life is initially 1.3 days, and is 2.4 days after administration for more than 1 year. The blood–brain barrier permits only slow passage of lithium, which is why a single overdose does not necessarily cause toxicity and why long-term lithium intoxication is slow to resolve. The elimination half-life of lithium is 18 to 24 hours in young adults, but is shorter in children and longer in elderly persons. Renal clearance of lithium is decreased with renal insufficiency. Equilibrium is reached after 5 to 7 days of regular intake. Obesity is associated with higher rates of lithium clearance. The excretion of lithium is complex during pregnancy; excretion increases during pregnancy but decreases after delivery. Lithium is excreted in breast milk and in insignificant amounts in the feces and sweat. Thyroid and renal concentrations of lithium are higher than serum levels.

An explanation for the mood-stabilizing effects of lithium remains elusive. Theories include alterations of ion transport and effects on neurotransmitters and neuropeptides,
signal transduction pathways, and second messenger systems.

**THERAPEUTIC INDICATIONS**

**Bipolar I Disorder**

**Manic Episodes.** Lithium controls acute mania and prevents relapse in about 80 percent of persons with bipolar I disorder and in a somewhat smaller percentage of persons with mixed (mania and depression) episodes, rapid-cycling bipolar disorder, or mood changes in encephalopathy. Lithium has a relatively slow onset of action when used and exerts its antimanic effects over 1 to 3 weeks. Thus, a benzodiazepine, dopamine receptor antagonist (DRA), serotonin–dopamine antagonist (SDA), or valproic acid is usually administered for the first few weeks. Patients with mixed or dysphoric mania, rapid cycling, comorbid substance abuse, or organicity respond less well to lithium than those with classic mania.

**Bipolar Depression.** Lithium has been shown to be effective in the treatment of depression associated with bipolar I disorder, as well as in the role of add-on therapy for patients with severe major depressive disorder. Augmentation of lithium therapy with valproic acid (Depakene) or carbamazepine (Tegretol) is usually well tolerated, with little risk of precipitation of mania.

When a depressive episode occurs in a person taking maintenance lithium, the differential diagnosis should include lithium-induced hypothyroidism, substance abuse, and lack of compliance with the lithium therapy. Possible treatment approaches include increasing the lithium concentration (up to 1 to 1.2 mEq/L); adding supplemental thyroid hormone (e.g., 25 μg a day of liothyronine [Cytomel]), even in the presence of normal findings on thyroid function tests; augmentation with valproate or carbamazepine; the judicious use of antidepressants; or electroconvulsive therapy (ECT). After the acute depressive episode resolves, other therapies should be tapered in favor of lithium monotherapy, if clinically tolerated.

**Maintenance.** Maintenance treatment with lithium markedly decreases the frequency, severity, and duration of manic and depressive episodes in persons with bipolar I disorder. Lithium provides relatively more effective prophylaxis for mania than for depression, and supplemental antidepressant strategies may be necessary either intermittently or continuously. Lithium maintenance is almost always indicated after the first episode of bipolar I disorder, depression or mania, and should be considered after the first episode for adolescents or for persons who have a family history of bipolar I disorder. Others who benefit from lithium maintenance are those who have poor support systems, had no precipitating factors for the first episode, have a high suicide risk, had a sudden onset of the first episode, or had a first episode of mania. Clinical studies have shown that lithium reduces the incidence of suicide in bipolar I disorder patients sixfold or sevenfold. Lithium is also an effective treatment for persons with severe cyclothymic...
disorder.
Initiating maintenance therapy after the first manic episode is considered a wise approach based on several observations. First, each episode of mania increases the risk of subsequent episodes. Second, among people responsive to lithium, relapses are 28 times more likely after lithium use is discontinued. Third, case reports describe persons who initially responded to lithium, discontinued taking it, and then had a relapse but no longer responded to lithium in subsequent episodes. Continued maintenance treatment with lithium is often associated with increasing efficacy and reduced mortality. Therefore, an episode of depression or mania that occurs after a relatively short time of lithium maintenance does not necessarily represent treatment failure. However, lithium treatment alone may begin to lose its effectiveness after several years of successful use. If this occurs, then supplemental treatment with carbamazepine or valproate may be useful.

Maintenance lithium dosages can often be adjusted to achieve plasma concentration somewhat lower than that needed for treatment of acute mania. If lithium use is to be discontinued, then the dosage should be slowly tapered. Abrupt discontinuation of lithium therapy is associated with an increased risk of recurrence of manic and depressive episodes.

Major Depressive Disorder
Lithium is effective in the long-term treatment of major depression, but it is not more effective than antidepressant drugs. The most common role for lithium in major depressive disorder is as an adjuvant to antidepressant use in persons who have failed to respond to the antidepressants alone. About 50 to 60 percent of antidepressant nonresponders do respond when lithium, 300 mg three times daily, is added to the antidepressant regimen. In some cases, a response may be seen within days, but most often, several weeks are required to see the efficacy of the regimen. Lithium alone may effectively treat depressed persons who have bipolar I disorder but have not yet had their first manic episode. Lithium has been reported to be effective in persons with major depressive disorder whose disorder has a particularly marked cyclicity.

Schizoaffective Disorder and Schizophrenia
Persons with prominent mood symptoms—either bipolar type or depressive type—with schizoaffective disorder are more likely to respond to lithium than those with predominant psychotic symptoms. Although SDAs and DRAs are the treatments of choice for persons with schizoaffective disorder, lithium is a useful augmentation agent. This is particularly true for persons whose symptoms are resistant to treatment with SDAs and DRAs. Lithium augmentation of an SDA or DRA treatment may be an effective treatment for persons with schizoaffective disorder even in the absence of a prominent mood disorder component. Some persons with schizophrenia who cannot take antipsychotic drugs may benefit from lithium treatment alone.
Other Indications

Over the years, reports have appeared about the use of lithium to treat a wide range of other psychiatric and nonpsychiatric conditions (Tables 29.19-1 and 29.19-2). The effectiveness and safety of lithium for most of these disorders have not been confirmed. Lithium has antiaggressive activity that is separate from its effects on mood. Aggressive outbursts in persons with schizophrenia, violent prison inmates, and children with conduct disorder and aggression, or self-mutilation in persons with mental retardation can sometimes be controlled with lithium.

PRECAUTIONS AND ADVERSE EFFECTS

More than 80 percent of patients taking lithium experience side effects. It is important to minimize the risk of adverse events through monitoring of lithium blood levels and to use appropriate pharmacological interventions to counteract unwanted effects when
they occur. The most common adverse effects are summarized in Table 29.19-3. Patient education can play an important role in reducing the incidence and severity of side effects. Patients taking lithium should be advised that changes in the body's water and salt content can affect the amount of lithium excreted, resulting in either increases or decreases in lithium concentrations. Excessive sodium intake (e.g., a dramatic dietary change) lowers lithium concentrations. Conversely, too little sodium (e.g., fad diets) can lead to potentially toxic concentrations of lithium. Decreases in body fluid (e.g., excessive perspiration) can lead to dehydration and lithium intoxication. Patients should report whenever medications are prescribed by another clinician because many commonly used agents can affect lithium concentrations.

GFR, glomerular filtration rate.

### Cardiac Effects
Lithium can cause diffuse slowing, widening of frequency spectrum, and potentiation and disorganization of background rhythm on electrocardiography (ECG). Bradycardia and cardiac arrhythmias may occur, especially in people with cardiovascular disease. Lithium infrequently reveals Brugada syndrome, an inherited, life-threatening heart problem that some people may have without knowing it. It can cause a serious abnormal heartbeat and other symptoms (such as severe dizziness, fainting, shortness of breath) that need medical attention right away. Before starting lithium treatment, clinicians should ask about known heart conditions, unexplained fainting, and family history of problems or sudden unexplained death before age 45.

### Gastrointestinal Effects
Gastrointestinal (GI) symptoms—which include nausea, decreased appetite, vomiting, and diarrhea—can be diminished by dividing the dosage, administering the lithium with food, or switching to another lithium preparation. The lithium preparation least likely to cause diarrhea is lithium citrate. Some lithium preparations contain lactose, which can cause diarrhea in lactose-intolerant persons. Persons taking slow-release formulations of lithium who experience diarrhea caused by unabsorbed medication in the lower part of the GI tract may experience less diarrhea than with standard-release preparations. Diarrhea may also respond to antidiarrheal preparations such as loperamide (Imodium, Kaopectate), bismuth subsalicylate (Pepto-Bismol), or diphenoxylate with atropine (Lomotil).

Weight Gain
Weight gain results from a poorly understood effect of lithium on carbohydrate metabolism. Weight gain can also result from lithium-induced hypothyroidism, lithium-induced edema, or excessive consumption of soft drinks and juices to quench lithium-induced thirst.

Neurological Effects
Tremor. A lithium-induced postural tremor may occur that is usually 8 to 12 Hz and is most notable in outstretched hands, especially in the fingers, and during tasks involving fine manipulations. The tremor can be reduced by dividing the daily dosage, using a sustained-release formulation, reducing caffeine intake, reassessing the concomitant use of other medicines, and treating comorbid anxiety. β-Adrenergic receptor antagonists, such as propranolol, 30 to 120 mg a day in divided doses, and primidone (Mysoline), 50 to 250 mg a day, are usually effective in reducing the tremor. In persons with hypokalemia, potassium supplementation may improve the tremor. When a person taking lithium has a severe tremor, the possibility of lithium toxicity should be suspected and evaluated.

Cognitive Effects. Lithium use has been associated with dysphoria, lack of spontaneity, slowed reaction times, and impaired memory. The presence of these symptoms should be noted carefully because they are a frequent cause of noncompliance. The differential diagnosis for such symptoms should include depressive disorders, hypothyroidism, hypercalcemia, other illnesses, and other drugs. Some, but not all, persons have reported that fatigue and mild cognitive impairment decrease with time.

Other Neurological Effects. Uncommon neurological adverse effects include symptoms of mild parkinsonism, ataxia, and dysarthria, although the last two symptoms may also be attributable to lithium intoxication. Lithium is rarely associated with the development of peripheral neuropathy, benign intracranial hypertension (pseudotumor cerebri), findings resembling myasthenia gravis, and increased risk of seizures.
Renal Effect

The most common adverse renal effect of lithium is polyuria with secondary polydipsia. The symptom is particularly a problem in 25 to 35 percent of persons taking lithium who may have a urine output of more than 3 L a day (reference range: 1 to 2 L a day). The polyuria primarily results from lithium antagonism to the effects of antidiuretic hormone, which thus causes diuresis. When polyuria is a significant problem, the person’s renal function should be evaluated and followed up with 24-hour urine collections for creatinine clearance determinations. Treatment consists of fluid replacement, the use of the lowest effective dosage of lithium, and single daily dosing of lithium. Treatment can also involve the use of a thiazide or potassium-sparing diuretic—for example, amiloride (Midamor), spironolactone (Aldactone), triamterene (Dyrenium), or amiloride–hydrochlorothiazide (Moduretic). If treatment with a diuretic is initiated, the lithium dosage should be halved, and the diuretic should not be started for 5 days, because the diuretic is likely to increase lithium retention.

The most serious renal adverse effects, which are rare and associated with continuous lithium administration for 10 years or more, involve appearance of nonspecific interstitial fibrosis, associated with gradual decreases in glomerular filtration rate and increases in serum creatinine concentrations, and rarely with renal failure. Lithium is occasionally associated with nephrotic syndrome and features of distal renal tubular acidosis. Another pathological finding in patients with lithium nephropathy is the presence of microcysts. Magnetic resonance imaging (MRI) can be used to demonstrate renal microcysts secondary to chronic lithium nephropathy and therefore avoid renal biopsy. It is prudent for persons taking lithium to check their serum creatinine concentration, urine chemistries, and 24-hour urine volume at 6-month intervals. If creatinine levels do rise, then more frequent monitoring and MRI might be considered.

Thyroid Effects

Lithium causes a generally benign and often transient diminution in the concentrations of circulating thyroid hormones. Reports have attributed goiter (5 percent of persons), benign reversible exophthalmos, hyperthyroidism, and hypothyroidism (7 to 10 percent of persons) to lithium treatment. Lithium-induced hypothyroidism is more common in women (14 percent) than in men (4.5 percent). Women are at highest risk during the first 2 years of treatment. Persons taking lithium to treat bipolar disorder are twice as likely to develop hypothyroidism if they develop rapid cycling. About 50 percent of persons receiving long-term lithium treatment have laboratory abnormalities, such as an abnormal thyrotropin-releasing hormone response, and about 30 percent have elevated concentrations of thyroid-stimulating hormone (TSH). If symptoms of hypothyroidism are present, replacement with levothyroxine (Synthroid) is indicated. Even in the absence of hypothyroid symptoms, some clinicians treat persons with significantly elevated TSH concentrations with levothyroxine. In lithium-treated persons, TSH concentrations should be measured every 6 to 12 months. Lithium-induced
Cardiac Effects

The cardiac effects of lithium resemble those of hypokalemia on ECG. They are caused by the displacement of intracellular potassium by the lithium ion. The most common changes on the ECG are T-wave flattening or inversion. The changes are benign and disappear after lithium is excreted from the body.

Lithium depresses the pacemaking activity of the sinus node, sometimes resulting in sinus dysrhythmias, heart block, and episodes of syncope. Lithium treatment, therefore, is contraindicated in persons with sick sinus syndrome. In rare cases, ventricular arrhythmias and congestive heart failure have been associated with lithium therapy. Lithium cardiotoxicity is more prevalent in persons on a low-salt diet, those taking certain diuretics or angiotensin-converting enzyme inhibitors (ACEIs), and those with fluid–electrolyte imbalances or any renal insufficiency.

Dermatological Effects

Dermatological effects may be dose dependent. They include acneiform, follicular, and maculopapular eruptions; pretibial ulcerations; and worsening of psoriasis. Occasionally, aggravated psoriasis or acneiform eruptions may force the discontinuation of lithium treatment. Alopecia has also been reported. Persons with many of those conditions respond favorably to changing to another lithium preparation and the usual dermatological measures. Lithium concentrations should be monitored if tetracycline is used for the treatment of acne because it can increase the retention of lithium.

Lithium Toxicity and Overdoses

The early signs and symptoms of lithium toxicity include neurological symptoms, such as coarse tremor, dysarthria, and ataxia; GI symptoms; cardiovascular changes; and renal dysfunction. The later signs and symptoms include impaired consciousness, muscular fasciculations, myoclonus, seizures, and coma. Signs and symptoms of lithium toxicity are outlined in Table 29.19-4. Risk factors include exceeding the recommended dosage, renal impairment, low-sodium diet, drug interaction, and dehydration. Elderly persons are more vulnerable to the effects of increased serum lithium concentrations. The greater the degree and duration of elevated lithium concentrations, the worse the symptoms of lithium toxicity.

Table 29.19-4

| Signs and Symptoms of Lithium Toxicity |
Lithium toxicity is a medical emergency, potentially causing permanent neuronal damage and death. In cases of toxicity (Table 29.19-5), lithium should be stopped and dehydration treated. Unabsorbed lithium can be removed from the GI tract by ingestion of sodium polystyrene sulfonate (Kayexalate) or polyethylene glycol solution (GoLYTELY), but not activated charcoal. Ingestion of a single large dose may create clumps of medication in the stomach, which can be removed by gastric lavage with a wide-bore tube. The value of forced diuresis is still debated. In severe cases, hemodialysis rapidly removes excessive amounts of serum lithium. Postdialysis serum lithium concentrations may increase as lithium is redistributed from tissues to blood, so repeat dialysis may be needed. Neurological improvement may lag behind clearance of serum lithium by several days because lithium crosses the blood–brain barrier slowly.

Table 29.19-5
Management of Lithium Toxicity

1. Contact personal physician or go to a hospital emergency department.
2. Lithium should be discontinued.
3. Vital signs and a neurological examination with complete formal mental status examination.
4. Lithium level, serum electrolytes, renal function tests, and ECG.
5. Emesis, gastric lavage, and absorption with activated charcoal.
6. For any patient with a serum lithium level greater than 4.0 mEq/L, hemodialysis.

ECG, electrocardiography.
Adolescents
The serum lithium concentrations for adolescents are similar to those for adults. Weight gain and acne associated with lithium use can be particularly troublesome to adolescents.

Elderly Persons
Lithium is a safe and effective drug for elderly persons. However, the treatment of elderly persons taking lithium may be complicated by the presence of other medical illnesses, decreased renal function, special diets that affect lithium clearance, and generally increased sensitivity to lithium. Elderly persons should initially be given low dosages, their dosages should be switched less frequently than those of younger persons, and a longer time must be allowed for renal excretion to equilibrate with absorption before lithium can be assumed to have reached its steady-state concentrations.

Pregnant Women
Lithium should not be administered to pregnant women in the first trimester because of the risk of birth defects. The most common malformations involve the cardiovascular system, most commonly Ebstein’s anomaly of the tricuspid valves. The risk of Ebstein’s malformation in lithium-exposed fetuses is one in 1,000, which is 20 times the risk in the general population. The possibility of fetal cardiac anomalies can be evaluated with fetal echocardiography. The teratogenic risk of lithium (4 to 12 percent) is higher than that for the general population (2 to 3 percent) but appears to be lower than that associated with the use of valproate or carbamazepine. A woman who continues to take lithium during pregnancy should use the lowest effective dosage. The maternal lithium concentration must be monitored closely during pregnancy, and especially after pregnancy, because of the significant decrease in renal lithium excretion as renal function returns to normal in the first few days after delivery. Adequate hydration can reduce the risk of lithium toxicity during labor. Lithium prophylaxis is recommended for all women with bipolar disorder as they enter the postpartum period. Lithium is excreted into breast milk and should be taken by a nursing mother only after careful evaluation of potential risks and benefits. Signs of lithium toxicity in infants include lethargy, cyanosis, abnormal reflexes, and sometimes hepatomegaly.

Miscellaneous Effects
Lithium should be used with caution in diabetic persons, who should monitor their blood glucose concentrations carefully to avoid diabetic ketoacidosis. Benign, reversible leukocytosis is commonly associated with lithium treatment. Dehydrated, debilitated, and medically ill persons are most susceptible to adverse effects and toxicity.

DRUG INTERACTIONS
Lithium drug interactions are summarized in Table 29.19-6.

</table>

NSAID, nonsteroidal anti-inflammatory drug; ACEI, angiotensin-converting enzyme inhibitor.

Lithium is commonly used in conjunction with DRAs. This combination is typically effective and safe. However, coadministration of higher dosages of a DRA and lithium may result in a synergistic increase in the symptoms of lithium-induced neurological side effects and neuroleptic extrapyramidal symptoms. In rare instances, encephalopathy has been reported with this combination.

The coadministration of lithium and carbamazepine, lamotrigine, valproate, and clonazepam may increase lithium concentrations and aggravate lithium-induced neurological adverse effects. Treatment with the combination should be initiated at slightly lower dosages than usual, and the dosages should be increased gradually. Changes from one to another treatment for mania should be made carefully, with as little temporal overlap between the drugs as possible.

Most diuretics (e.g., thiazide and potassium sparing) can increase lithium concentrations; when treatment with such a diuretic is stopped, the clinician may need to increase the person’s daily lithium dosage. Osmotic and loop diuretics, carbonic anhydrase inhibitors, and xanthines (including caffeine) may reduce lithium concentrations to below therapeutic concentrations. Whereas ACEIs may cause an increase in lithium concentrations, the AT$_1$ angiotensin II receptor inhibitors losartan
(Cozaar) and irbesartan (Avapro) do not alter lithium concentrations. A wide range of nonsteroidal anti-inflammatory drugs (NSAIDs) can decrease lithium clearance, thereby increasing lithium concentrations. These drugs include indomethacin (Indocin), phenylbutazone (Azolid), diclofenac (Voltaren), ketoprofen (Orudis), oxyphenbutazone (Oxalid), ibuprofen (Motrin, Advil), piroxicam (Feldene), and naproxen (Naprosyn). Aspirin and sulindac (Clinoril) do not affect lithium concentrations.

The coadministration of lithium and quetiapine (Seroquel) may cause somnolence but is otherwise well tolerated. The coadministration of lithium and ziprasidone (Geodon) may modestly increase the incidence of tremor. The coadministration of lithium and calcium channel inhibitors should be avoided because of potentially fatal neurotoxicity.

A person taking lithium who is about to undergo ECT should discontinue taking lithium 2 days before beginning ECT to reduce the risk of delirium.

LABORATORY INTERFERENCES
Lithium does not interfere with any laboratory tests, but lithium-induced alterations include an increased white blood cell count, decreased serum thyroxine, and increased serum calcium. Blood collected in a lithium–heparin anticoagulant tube will produce falsely elevated lithium concentrations.

DOSAGE AND CLINICAL GUIDELINES

Initial Medical Workup
All patients should have a routine laboratory workup and physical examination before being started on lithium. The laboratory tests should include serum creatinine concentration (or a 24-hour urine creatinine if the clinician has any reason to be concerned about renal function), electrolytes, thyroid function (TSH, T₃ [triiodothyronine], and T₄ [thyroxine]), a complete blood count (CBC), ECG, and a pregnancy test in women of childbearing age.

Dosage Recommendations
Lithium formulations include immediate-release 150, 300, and 600 mg lithium carbonate capsules (Eskalith and generic), 300 mg lithium carbonate tablets (Lithotabs), 450 mg controlled-release lithium carbonate capsules (Eskalith CR and Lithonate), and 8 mEq/5 mL of lithium citrate syrup.

The starting dosage for most adults is 300 mg of the regular-release formulation three times daily. The starting dosage for elderly persons or persons with renal impairment should be 300 mg once or twice daily. After stabilization, dosages between 900 and 1,200 mg a day usually produce a therapeutic plasma concentration of 0.6 to 1 mEq/L, and a daily dose of 1,200 to 1,800 mg usually produces a therapeutic concentration of 0.8 to 1.2 mEq/L. Maintenance dosing can be given either in two or three divided doses of the regular-release formulation or in a single dosage of the sustained-release
formulation equivalent to the combined daily dosage of the regular-release formulation. The use of divided doses reduces gastric upset and avoids single high-peak lithium concentrations. Discontinuation of lithium should be gradual to minimize the risk of early recurrence of mania and to permit recognition of early signs of recurrence.

**Laboratory Monitoring**

The periodic measurement of serum lithium concentration is an essential aspect of patient care, but it should always be combined with sound clinical judgment. A laboratory report listing the therapeutic range as 0.5 to 1.5 mEq/L may lull a clinician into disregarding early signs of lithium intoxication in patients whose levels are less than 1.5 mEq/L. Clinical toxicity, especially in elderly persons, has been well documented within this so-called therapeutic range.

Regular monitoring of serum lithium concentrations is essential. Lithium levels should be obtained every 2 to 6 months except when there are signs of toxicity, during dosage adjustments, and in persons suspected to be noncompliant with the prescribed dosages. Under these circumstances, levels may be done weekly. Baseline ECG studies are essential, and should be repeated annually.

When obtaining blood for lithium levels, patients should be at steady-state lithium dosing (usually after 5 days of constant dosing), preferably using a twice-daily or thrice-daily dosing regimen, and the blood sample must be drawn 12 hours (±30 minutes) after a given dose. Lithium concentrations 12 hours postdose in persons treated with sustained-release preparations are generally about 30% higher than the corresponding concentrations obtained from those taking the regular-release preparations. Because available data are based on a sample population following a multiple-dosage regimen, regular-release formulations given at least twice daily should be used for initial determination of the appropriate dosages. Factors that may cause fluctuations in lithium measurements include dietary sodium intake, mood state, activity level, body position, and use of an improper blood sample tube.

Laboratory values that do not seem to correspond to clinical status may result from the collection of blood in a tube with a lithium–heparin anticoagulant (which can give results falsely elevated by as much as 1 mEq/L) or aging of the lithium ion–selective electrode (which can cause inaccuracies of up to 0.5 mEq/L). After the daily dose has been set, it is reasonable to change to the sustained-release formulation given once daily.

Effective serum concentrations for mania are 1.0 to 1.5 mEq/L, a level associated with 1,800 mg a day. The recommended range for maintenance treatment is 0.4 to 0.8 mEq/L, which is usually achieved with a daily dose of 900 to 1,200 mg. A small number of persons will not achieve therapeutic benefit with a lithium concentration of 1.5 mEq/L, yet will have no signs of toxicity. For such persons, titration of the lithium dosage to achieve a concentration above 1.5 mEq/L may be warranted. Some patients can be maintained at concentrations below 0.4 mEq/L. There may be considerable variation from patient to patient, so it is best to follow the maxim “treat the patient, not
the laboratory results.” The only way to establish an optimal dose for a patient may be through trial and error.

Package inserts (U.S.) for lithium products list effective serum concentrations for mania between 1.0 and 1.5 mEq/L (usually achieved with 1,800 mg of lithium carbonate daily) and for long-term maintenance between 0.6 and 1.2 mEq/L (usually achieved with 900 to 1,200 mg of lithium carbonate daily). The dose–blood level relationship may vary considerably from patient to patient. The likelihood of achieving a response at levels above 1.5 mEq/L is usually outweighed greatly by the increased risk of toxicity, although rarely a patient may both require and tolerate a higher-than-usual blood concentration.

What constitutes the lower end of the therapeutic range remains a matter of debate. A prospective 3-year study found patients who maintained a concentration between 0.4 and 0.6 mEq/L (mean 0.54) were 2.6 times more likely to relapse than those who maintained between 0.8 and 1.0 mEq/L (mean 0.83). However, the higher blood concentrations produced more adverse effects and were less well tolerated.

If there is no response after 2 weeks at a concentration that is beginning to cause adverse effects, then the person should taper off lithium over 1 to 2 weeks and other mood-stabilizing drugs should be tried.

**Patient Education**

Lithium has a narrow therapeutic index, and many factors can upset the balance between lithium concentrations that are well tolerated and therapeutic, and those that produce side effects or toxicity. It is thus imperative that persons taking lithium be educated about signs and symptoms of toxicity, factors that affect lithium levels, how and when to obtain laboratory testing, and the importance of regular communication with the prescribing physician. Lithium concentrations can be disrupted by common factors such as excessive sweating from ambient heat or exercise or use of widely prescribed agents such as ACEIs or nonsteroidal anti-inflammatory drugs (NSAIDs). Patients may stop taking their lithium because they are feeling well or because they are experiencing side effects. They should be advised against discontinuing or modifying their lithium regimen. Table 29.19-7 lists some important instructions for patients.

| Table 29.19-7 |
| Instructions to Patients Taking Lithium |
Lithium can be remarkably effective in treating your disorder. If not used appropriately and not monitored closely, it can be ineffective and potentially harmful. It is important to keep the following instructions in mind.

**Dosing**
Take lithium exactly as directed by your doctor—never take more or less than the prescribed dose.
Do not stop taking without speaking to your doctor.
If you miss a dose, take it as soon as possible. If it is within 4 hours of the next dose, skip the missed dose (about 6 hours in the case of extended-release or slow-release preparations). Never double up doses.

**Blood Tests**
Comply with the schedule of recommended regular blood tests. Despite their inconvenience and discomfort, your lithium blood levels, thyroid function, and kidney status need to be monitored as long as you take lithium.
When going to have lithium levels checked, you should have taken your last lithium dose 12 hours earlier.

**Use of Other Medications**
Do not start any prescription or over-the-counter medications without telling your doctor.
Even drugs such as ibuprofen (Advil, Motrin) and naproxen (Aleve) can significantly increase lithium levels.

**Diet and Fluid Intake**
Avoid sudden changes in your diet or fluid intake. If you do go on a diet, your doctor may need to increase the frequency of blood tests.
Caffeine and alcohol act as diuretics and can lower your lithium concentrations.
During treatment with lithium, it is recommended that you drink 2 or 3 quarts of fluid daily and use normal amounts of salt.
Inform your doctor if you start or stop a low-salt diet.

**Recognizing Potential Problems**
If you engage in vigorous exercise or have an illness that causes sweating, vomiting, or diarrhea, consult your doctor because these might affect lithium levels.
Nausea, constipation, shakiness, increased thirst, frequency of urination, weight gain, or swelling of the extremities should be reported to your doctor.
Blurred vision, confusion, loss of appetite, diarrhea, vomiting, muscle weakness, lethargy, shakiness, slurred speech, dizziness, loss of balance, inability to urinate, or seizures could indicate severe toxicity and should prompt immediate medical attention.

**REFERENCES**
29.20 Melatonin Agonists: Ramelteon and Melatonin

There are two melatonin receptor agonists commercially available in the United States: (1) melatonin, a dietary supplement available in various preparations in health food stores, and not under Food and Drug Administration (FDA) regulations; (2) and ramelteon (Rozerem), an FDA-approved drug for the treatment of insomnia characterized by difficulties with sleep onset. Both exogenous melatonin and ramelteon are thought to exert their effects by interaction with central melatonin receptors.

**RAMELTEON**

Ramelteon (Rozerem) is a melatonin receptor agonist used to treat sleep-onset insomnia. Unlike the benzodiazepines, ramelteon has no appreciable affinity for the γ-aminobutyric acid (GABA) receptor complex.
Pharmacological Actions

Ramelteon essentially mimics melatonin’s sleep-promoting properties and has high affinity for melatonin MT1 and MT2 receptors in the brain. These receptors are thought to be critical in the regulation of the body’s sleep–wake cycle.

Ramelteon is rapidly absorbed and eliminated over a dose range of 4 to 64 mg. Maximum plasma concentration \( (C_{\text{max}}) \) is reached approximately 45 minutes after administration, and the elimination half-life is 1 to 2.6 hours. The total absorption of ramelteon is at least 84%, but extensive first-pass metabolism results in a bioavailability of approximately 2%. Ramelteon is metabolized primarily through the cytochrome P450 (CYP)1A2 pathway and eliminated principally in urine. Repeated once-daily dosing does not appear to result in accumulation, likely because of the compound’s short half-life.

Therapeutic Indications

Ramelteon was approved by the FDA for the treatment of insomnia characterized by difficulty with sleep onset. Potential off-label use is centered on application in circadian rhythm disorders, predominantly jet lag, delayed sleep phase syndrome, and shift work sleep disorder.

Clinical trials and animal studies have failed to demonstrate evidence of rebound insomnia of withdrawal effects.

Precautions and Adverse Events

Headache is the most common side effect of ramelteon. Other adverse effects may include somnolence, fatigue, dizziness, worsening insomnia, depression, nausea, and diarrhea. The drug should not be used in patients with severe hepatic impairment. It is also not recommended in patients with severe sleep apnea or severe chronic obstructive pulmonary disease. Prolactin levels may be increased in women. The drug should be used with caution, if at all, in nursing mothers and pregnant women.

Ramelteon has been found to sometimes decrease blood cortisol and testosterone and to increase prolactin. Female patients should be monitored for cessation of menses and of galactorrhea, decreased libido, and fertility problems. The safety and effectiveness of ramelteon in children has not been established.

Drug Interactions

CYP1A2 is the major isozyme involved in the hepatic metabolism of ramelteon. Accordingly, fluvoxamine (Luvox) and other CYP1A2 inhibitors may increase side effects of ramelteon.

Ramelteon should be administered with caution in patients taking CYP1A2 inhibitors, strong CYP3A4 inhibitors such as ketoconazole, and strong CYP2C inhibitors such as fluconazole (Diflucan). No clinically meaningful interactions were found when
Ramelteon was coadministered with omeprazole, theophylline, dextromethorphan, midazolam, digoxin, and warfarin.

**Dosing and Clinical Guidelines**

The usual dose of ramelteon is 8 mg within 30 minutes of going to bed. It should not be taken with or immediately after high-fat meals.

**MELATONIN**

Melatonin (N-acetyl-5-methoxytryptamine) is a hormone produced mainly at night in the pineal gland. Ingested melatonin can reach and bind to melatonin-binding sites in the brains of mammals, and produce somnolence when used at high doses. Melatonin is available as a dietary supplement and is not a medication. Few well-controlled clinical trials have been conducted to determine its effectiveness in treating such conditions as insomnia, jet lag, and sleep disturbances related to shift work.

**Pharmacological Actions**

Melatonin’s secretion is stimulated by the dark and inhibited by the light. It is naturally synthesized from the amino acid tryptophan, which is converted to serotonin and finally converted to melatonin. The suprachiasmatic nuclei (SCN) of the hypothalamus have melatonin receptors, and melatonin may have a direct action on SCN to influence circadian rhythms, which are relevant for jet lag and sleep disturbances. In addition to the pineal gland, melatonin is also produced in the retina and gastrointestinal tract.

Melatonin has a very short half-life of 0.5 to 6 minutes. Plasma concentrations are a function of the dose administered and the endogenous rhythm. Approximately 90 percent of melatonin is cleared through first-pass metabolism by way of the CYP1A1 and CYP1A2 pathways. Elimination occurs principally in urine.

Exogenous melatonin interacts with the melatonin receptors that suppress neuronal firing and promote sleep. There does not appear to be a dose–response relationship between exogenous melatonin administrations and sleep effects.

**Therapeutic Indications**

Melatonin is not regulated by the FDA. Individuals have used exogenous melatonin to address sleep difficulties (insomnia, circadian rhythm disorders), cancer (breast, prostate, colorectal), seizures, depression, anxiety, and seasonal affective disorder. Some studies suggest that exogenous melatonin may have some antioxidant effects and antiaging properties.

**Precautions and Adverse Reactions**

Adverse events associated with melatonin include fatigue, dizziness, headache, irritability, and somnolence. Disorientation, confusion, sleepwalking, vivid dreams, and
nightmares have also been observed, often with effects resolving after melatonin administration was suspended.

Melatonin may reduce fertility in both men and women. In men, exogenous melatonin reduces sperm motility, and long-term administration has been shown to inhibit testicular aromatase levels. In women, exogenous melatonin may inhibit ovarian function and for that reason it has been evaluated as a contraceptive, but with inconclusive results.

Drug Interactions
As a dietary supplement preparation, exogenous melatonin is not regulated by the FDA and has not been subjected to the same type of drug interaction studies that were performed for ramelteon. Caution is suggested in coadministering melatonin with blood thinners (e.g., warfarin [Coumadin], aspirin, and heparin), antiseizure medications, and medications that lower blood pressure.

Laboratory Interference
Melatonin is not known to interfere with any commonly used clinical laboratory tests.

Dosage and Administration
Over-the-counter melatonin is available in the following formulations: 1, 2.5, 3, and 5 mg capsules; 1 mg/4 mL liquid; 0.5 and 3 mg lozenges; 2.5 mg sublingual tablets; and 1, 2, and 3 mg timed-release tablets.

Standard recommendations are to take the desired melatonin dose at bedtime, but some evidence from clinical trials suggests that dosing up to 2 hours before habitual bedtime may produce greater improvement in sleep onset.

Agomelatine (Valdoxan)
Agomelatine is structurally related to melatonin and is used in Europe as a treatment for major depressive disorder. It acts as an agonist at melatonin (MT1 and MT2) receptors. It also acts as a serotonin antagonist. Analysis of agomelatine clinical trial data raised serious questions about the efficacy and safety of the drug. The drug is not being marketed in the United States.

REFERENCES

29.21 Mirtazapine

Mirtazapine (Remeron) is unique among drugs used to treat major depression in that it increases both norepinephrine and serotonin through a mechanism other than reuptake blockade (as in the case of tricyclic agents or SSRIs) or monoamine oxidase inhibition (as in the case of phenelzine or tranylcypromine). Mirtazapine is also more likely to reduce rather than cause nausea and diarrhea, the result of its effects on serotonin 5-HT3 receptors. Characteristic side effects include increased appetite and sedation.

**PHARMACOLOGIC ACTIONS**
Mirtazapine is administered orally and is rapidly and completely absorbed. It has a half-life of about 30 hours. Peak concentration is achieved within 2 hours of ingestion, and steady state is reached after 6 days. Plasma clearance may be slowed up to 30 percent in persons with impaired hepatic function, up to 50 percent in those with impaired renal function, up to 40 percent slower in elderly men, and up to 10 percent slower in elderly women.

The mechanism of action of mirtazapine is antagonism of central presynaptic $\alpha_2$-adrenergic receptors and blockade of postsynaptic serotonin 5-HT$_2$ and 5-HT$_3$ receptors. The $\alpha_2$-adrenergic receptor antagonism causes increased firing of norepinephrine and serotonin neurons. The potent antagonist of serotonin 5-HT$_2$ and 5-HT$_3$ receptors serves to decrease anxiety, relieve insomnia, and stimulate appetite. Mirtazapine is a potent antagonist of histamine H$_1$ receptors and is a moderately potent antagonist at $\alpha_1$-adrenergic and muscarinic-cholinergic receptors.

**THERAPEUTIC INDICATIONS**

Mirtazapine is effective for the treatment of depression. It is highly sedating, making it a reasonable choice for use in depressed patients with severe or long-standing insomnia. Some patients find the residual daytime sedation associated with initiation of treatment to be quite pronounced. However, the more extreme sedating properties of the drug generally lessen over the first week of treatment. Combined with the tendency to sometimes cause a ravenous appetite, mirtazapine is well suited for depressed patients with melancholic features such as insomnia, weight loss, and agitation. Elderly depressed patients in particular are good candidates for mirtazapine; young adults are more likely to object to this side effect profile.

Mirtazapine’s blockade of 5-HT$_3$ receptors, a mechanism associated with medications used to combat the severe gastrointestinal side effects of cancer chemotherapy agents, has led to the use of the drug in a similar role. In this population, sedation and stimulation of appetite clearly could be seen as being beneficial instead of unwelcome side effects.

Mirtazapine is often combined with SSRIs or venlafaxine to augment antidepressant response or counteract serotonergic side effects of those drugs, particularly nausea, agitation, and insomnia. Mirtazapine has no significant pharmacokinetic interactions with other antidepressants.

**PRECAUTIONS AND ADVERSE REACTIONS**

Somnolence, the most common adverse effect of mirtazapine, occurs in more than 50 percent of persons (Table 29.21-1). Persons starting mirtazapine should thus exercise caution when driving or operating dangerous machinery and even when getting out of bed at night. This adverse effect is why mirtazapine is almost always given before sleep. Mirtazapine potentiates the sedative effects of other CNS depressants, so potentially
sedating prescription or over-the-counter drugs and alcohol should be avoided during use of mirtazapine. Mirtazapine also causes dizziness in 7 percent of persons. It does not appear to increase the risk for seizures. Mania or hypomania occurred in clinical trials at a rate similar to that of other antidepressant drugs.

Mirtazapine increases appetite in about one-third of patients. Mirtazapine may also increase serum cholesterol concentration to 20 percent or more above the upper limit of normal in 15 percent of persons and increase triglycerides to 500 mg/dL or more in 6 percent of persons. Elevations of alanine transaminase levels to more than three times the upper limit of normal were seen in 2 percent of mirtazapine-treated persons as opposed to 0.3 percent of placebo control subjects.

In limited premarketing experience, the absolute neutrophil count dropped to 500/mm$^3$ or less within 2 months of the onset of use in 0.3 percent of persons, some of whom developed symptomatic infections. This hematologic condition was reversible in all cases and was more likely to occur when other risk factors for neutropenia were present. Increases in the frequency of neutropenia have not, however, been reported during the extensive postmarketing period. Persons who develop fever, chills, sore throat, mucous membrane ulceration, or other signs of infection should nevertheless be evaluated medically. If a low white blood cell count is found, mirtazapine should be immediately discontinued, and the infectious disease status should be followed closely.

A small number of persons experience orthostatic hypotension while taking mirtazapine. Although no data exist regarding the effects on fetal development, mirtazapine should be used with caution during pregnancy.

Mirtazapine use by pregnant women has not been studied, but because the drug may be excreted in breast milk, it should not be taken by nursing mothers. Because of the risk of agranulocytosis associated with mirtazapine use, persons should be attuned to signs of infection. Because of the sedating effects of mirtazapine, persons should determine the degree to which they are affected before engaging in driving or other potentially dangerous activities.

**DRUG INTERACTIONS**

Mirtazapine can potentiate the sedation of alcohol and benzodiazepines. Mirtazapine
should not be used within 14 days of use of an MAOI.

LABORATORY INTERFERENCES

No laboratory interferences have yet been described for mirtazapine.

DOSAGE AND ADMINISTRATION

Mirtazapine is available in 15-, 30-, and 45-mg scored tablets. Mirtazapine is also available in 15-, 30-, and 45-mg orally disintegrating tablets for persons who have difficulty swallowing pills. If persons fail to respond to the initial dose of 15 mg of mirtazapine before sleep, the dose may be increased in 15-mg increments every 5 days to a maximum of 45 mg before sleep. Lower dosages may be necessary in elderly persons or persons with renal or hepatic insufficiency.

REFERENCES

29.22 Monoamine Oxidase Inhibitors

Introduced in the late 1950s, MAOIs were the first class of approved antidepressant drugs. The first of these drugs, isoniazid, was intended to be used as a treatment for tuberculosis, but its antidepressant properties were discovered by chance when some treated patients experienced elevation of mood during treatment. Despite their effectiveness, prescription of MAOIs as first-line agents has always been limited by concern about the development of potentially lethal hypertension and the consequent need for a restrictive diet. Use of MAOIs declined further after the introduction of the SSRIs and other new agents. They are now mainly relegated to use in treatment-resistant cases. Thus, the second-line status of MAOIs has less to do with considerations of efficacy than with concerns for safety. The currently available MAOIs include phenelzine (Nardil), isocarboxazid (Marplan), tranylcypromine (Parnate), rasagiline (Azilect), moclobemide (Manerix), and selegiline (Eldepryl).

Two subsequent advances in the field of antidepressant MAOIs involve the introduction of a selective reversible inhibitor of MAO_A (RIMA), moclobemide (Manerix), in the early 1990s into most countries except the United States, and in 2005, the introduction of a transdermal delivery form of selegiline (Emsam) in the United States that is used for the treatment of parkinsonism. Other RIMA agents, including brofaromine (Consonar) and befloxatone, have not been submitted for registration despite favorable outcomes in clinical trials.

PHARMACOLOGIC ACTIONS

Phenelzine, tranylcypromine, and isocarboxazid are readily absorbed after oral administration and reach peak plasma concentrations within 2 hours. Whereas their plasma half-lives are in the range of 2 to 3 hours, their tissue half-lives are considerably longer. Because they irreversibly inactivate MAOs, the therapeutic effect of a single dose of irreversible MAOIs may persist for as long as 2 weeks. The RIMA moclobemide is rapidly absorbed and has a half-life of 0.5 to 3.5 hours. Because it is a reversible inhibitor, moclobemide has a much briefer clinical effect after a single dose than do irreversible MAOIs.

The MAO enzymes are found on the outer membranes of mitochondria, where they degrade cytoplasmic and extraneuronal monoamine neurotransmitters such as norepinephrine, serotonin, dopamine, epinephrine, and tyramine. MAOIs act in the CNS, the sympathetic nervous system, the liver, and the GI tract. There are two types of MAOs, MAO_A and MAO_B. MAO_A primarily metabolizes norepinephrine, serotonin, and epinephrine; dopamine and tyramine are metabolized by both MAO_A and MAO_B.

The structures of phenelzine and tranylcypromine are similar to those of amphetamine and have similar pharmacologic effects in that they increase the release of
dopamine and norepinephrine with attendant stimulant effects on the brain.

**THERAPEUTIC INDICATIONS**

MAOIs are used for treatment of depression. Some research indicates that phenelzine is more effective than tricyclic antidepressants (TCAs) in depressed patients with mood reactivity, extreme sensitivity to interpersonal loss or rejection, prominent anergia, hyperphagia, and hypersomnia—a constellation of symptoms conceptualized as atypical depression. Evidence also suggests that MAOIs are more effective than TCAs as a treatment for bipolar depression.

Patients with panic disorder and social phobia respond well to MAOIs. MAOIs have also been used to treat bulimia nervosa, posttraumatic stress disorder (PTSD), anginal pain, atypical facial pain, migraine, attention-deficit/hyperactivity disorder (ADHD), idiopathic orthostatic hypotension, and depression associated with traumatic brain injury.

**PRECAUTIONS AND ADVERSE REACTIONS**

The most frequent adverse effects of MAOIs are orthostatic hypotension, insomnia, weight gain, edema, and sexual dysfunction. Orthostatic hypotension can lead to dizziness and falls. Thus, cautious upward tapering of the dosage should be used to determine the maximum tolerable dosage. Treatment for orthostatic hypotension includes avoidance of caffeine; intake of 2 L of fluid per day; addition of dietary salt or adjustment of antihypertensive drugs (if applicable); support stockings; and in severe cases, treatment with fludrocortisone (Florinef), a mineralocorticoid, 0.1 to 0.2 mg a day. Orthostatic hypotension associated with tranylcypromine use can usually be relieved by dividing the daily dosage.

Insomnia can be treated by dividing the dose, not giving the medication after dinner, and using trazodone (Desyrel) or a benzodiazepine hypnotic if necessary. Weight gain, edema, and sexual dysfunction often do not respond to any treatment and may warrant switching to another agent. When switching from one MAOI to another, the clinician should taper and stop use of the first drug for 10 to 14 days before beginning use of the second drug.

Paresthesias, myoclonus, and muscle pains are occasionally seen in persons treated with MAOIs. Paresthesias may be secondary to MAOI-induced pyridoxine deficiency, which may respond to supplementation with pyridoxine, 50 to 150 mg orally each day. Occasionally, persons complain of feeling drunk or confused, perhaps indicating that the dosage should be reduced and then increased gradually. Reports that the hydrazine MAOIs are associated with hepatotoxic effects are relatively uncommon. MAOIs are less cardiotoxic and less epileptogenic than are the tricyclic and tetracyclic drugs.

The most common adverse effects of the RIMA moclobemide are dizziness, nausea, and insomnia or sleep disturbance. RIMAs cause fewer GI adverse effects than do SSRIs. Moclobemide does not have adverse anticholinergic or cardiovascular effects, and it has not been reported to interfere with sexual function.
MAOIs should be used with caution by persons with renal disease, cardiovascular disease, or hyperthyroidism. MAOIs may alter the dosage of a hypoglycemic agent required by persons with diabetes. MAOIs have been particularly associated with induction of mania in persons in the depressed phase of bipolar I disorder and triggering of a psychotic decompensation in persons with schizophrenia. MAOIs are contraindicated during pregnancy, although data on their teratogenic risk are minimal. MAOIs should not be taken by nursing women because the drugs can pass into the breast milk.

**Tyramine-Induced Hypertensive Crisis**

The most worrisome side effect of MAOIs is the tyramine-induced hypertensive crisis. The amino acid tyramine is normally transformed via GI metabolism. However, MAOIs inactivate GI metabolism of dietary tyramine, thus allowing intact tyramine to enter the circulation. A hypertensive crisis may subsequently occur as a result of a powerful pressor effect of the amino acid. Tyramine-containing foods should be avoided for 2 weeks after the last dose of an irreversible MAOI to allow resynthesis of adequate concentrations of MAO enzymes.

Accordingly, foods rich in tyramine (Table 29.22-1) or other sympathomimetic amines, such as ephedrine, pseudoephedrine (Sudafed), or dextromethorphan (Trocal), should be avoided by persons who are taking irreversible MAOIs. Patients should be advised to continue the dietary restrictions for 2 weeks after they stop MAOI treatment to allow the body to resynthesize the enzyme. Bee stings may cause a hypertensive crisis. In addition to severe hypertension, other symptoms may include headache, stiff neck, diaphoresis, nausea, and vomiting. A patient with these symptoms should seek immediate medical treatment.

<table>
<thead>
<tr>
<th>Tyramine-Rich Foods to be Avoided in Planning Monoamine Oxidase Inhibitor Diets</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
</tr>
</tbody>
</table>
An MAOI-induced hypertensive crisis should be treated with α-adrenergic antagonists—for example, phentolamine (Regitine) or chlorpromazine (Thorazine). These drugs lower blood pressure within 5 minutes. IV furosemide (Lasix) can be used to reduce fluid load, and a β-adrenergic receptor antagonist can control tachycardia. A sublingual 10-mg dose of nifedipine (Procardia) can be given and repeated after 20 minutes. MAOIs should not be used by persons with thyrotoxicosis or pheochromocytoma.

The risk of tyramine-induced hypertensive crises is relatively low for persons who are taking RIMAs, such as moclobemide and befloxatone. These drugs have relatively little inhibitory activity for MAO\textsubscript{B}, and because they are reversible, normal activity of existing MAO\textsubscript{A} returns within 16 to 48 hours of the last dose of a RIMA. Therefore, the dietary restrictions are less stringent for RIMAs, applying only to foods containing high concentrations of tyramine, which need be avoided for 3 days after the last dose of a RIMA. A reasonable dietary recommendation for persons taking RIMAs is to avoid eating tyramine-containing foods 1 hour before and 2 hours after taking a RIMA.

Spontaneous, nontyramine-induced hypertensive crisis is a rare occurrence, usually shortly after the first exposure of an MAOI. Persons experiencing such a crisis should avoid MAOIs altogether.

**Withdrawal**

Abrupt cessation of regular doses of MAOIs may cause a self-limited discontinuation syndrome consisting of arousal, mood disturbances, and somatic symptoms. To avoid
these symptoms when discontinuing use to an MAOI, dosages should be gradually tapered over several weeks.

Overdose

There is often an asymptomatic period of 1 to 6 hours after an MAOI overdose before the occurrence of the symptoms of toxicity. MAOI overdose is characterized by agitation that can progress to coma with hyperthermia, hypertension, tachypnea, tachycardia, dilated pupils, and hyperactive deep tendon reflexes. Involuntary movements may be present, particularly in the face and the jaw. Acidification of the urine markedly hastens the excretion of MAOIs, and dialysis can be of some use. Phentolamine or chlorpromazine may be useful if hypertension is a problem. Moclobemide alone in overdose causes relatively mild and reversible symptoms.

DRUG INTERACTIONS

The major drug–drug interactions involving MAOIs are listed in Table 29.22-2. Most antidepressants as well as precursor agents should be avoided. Persons should be instructed to tell any other physicians or dentists who are treating them that they are taking an MAOI. MAOIs may potentiate the action of CNS depressants, including alcohol and barbiturates. MAOIs should not be coadministered with serotonergic drugs, such as SSRIs and clomipramine (Anafranil), because this combination can trigger a serotonin syndrome. Use of lithium or tryptophan with an irreversible MAOI may also induce a serotonin syndrome. Initial symptoms of a serotonin syndrome can include tremor, hypertonicity, myoclonus, and autonomic signs, which can then progress to hallucinosis, hyperthermia, and even death. Fatal reactions have occurred when MAOIs were combined with meperidine (Demerol) or fentanyl (Sublimaze).

Table 29.22-2
Drugs to be Avoided During Monoamine Oxidase Inhibitor Treatment (Part of Listing)
When switching from an irreversible MAOI to any other type of antidepressant drug, persons should wait at least 14 days after the last dose of the MAOI before beginning use of the next drug to allow replenishment of the body’s MAOs. When switching from an antidepressant to an irreversible MAOI, persons should wait 10 to 14 days (or 5 weeks for fluoxetine [Prozac]) before starting use of the MAOI to avoid drug–drug interactions. In contrast, MAO activity recovers completely 24 to 48 hours after the last dose of a RIMA.

The effects of the MAOIs on hepatic enzymes are poorly studied. Tranylcypromine inhibits CYP2C19. Moclobemide inhibits CYP2D6, CYP2C19, and CYP1A2 and is a substrate for 2C19.

Cimetidine (Tagamet) and fluoxetine significantly reduce the elimination of moclobemide. Modest doses of fluoxetine and moclobemide administered concurrently may be well tolerated, with no significant pharmacodynamic or pharmacokinetic interactions.

LABORATORY INTERFERENCES
MAOIs may lower blood glucose concentrations. MAOIs artificially raise urinary metanephrine concentrations and may cause a false-positive test result for pheochromocytoma or neuroblastoma. MAOIs have been reported to be associated with a minimal false elevation in thyroid function test results.

DOSAGE AND CLINICAL GUIDELINES
There is no definitive rationale for choosing one irreversible MAOI over another. Table
29.22-3 lists MAOI preparations and typical dosages. Phenelzine use should begin with a test dose of 15 mg on the first day. The dosage can be increased to 15 mg three times daily during the first week and increased by 15 mg a day each week thereafter until the dosage of 90 mg a day, in divided doses, is reached by the end of the fourth week. Tranylcypromine and isocarboxazid use should begin with a test dosage of 10 mg and may be increased to 10 mg three times daily by the end of the first week. Many clinicians and researchers have recommended upper limits of 50 mg a day for isocarboxazid and 40 mg a day for tranylcypromine. Administration of tranylcypromine in multiple small daily doses may reduce its hypotensive effects.

Even though coadministration of MAOIs with TCAs, SSRIs, or lithium is generally contraindicated, these combinations have been used successfully and safely to treat patients with refractory depression. However, they should be used with extreme caution.

Hepatic transaminase serum concentrations should be monitored periodically because of the potential for hepatotoxicity, especially with phenelzine and isocarboxazid. Elderly persons may be more sensitive to MAOI adverse effects than are younger adults. MAO activity increases with age, so MAOI dosages for elderly persons are the same as those required for younger adults. The use of MAOIs for children has had minimal study.

Studies have suggested that transdermal selegiline has antidepressant properties. Although selegiline is a type B inhibitor at low doses, it becomes less selective as the dose is increased.

**References**

Balu DT, Hoshaw BA, Malberg JE. Differential regulation of central BDNF protein levels by antidepressant and non-
Nefazodone (Serzone) and Trazodone (Desyrel, Oleptro) are mechanistically and structurally related drugs approved as treatments for depression. Nefazodone (Serzone) is an analog of trazodone. When nefazodone was introduced in 1995, there were expectations that it would become widely used because it did not cause the sexual side effects and sleep disruption associated with the selective SSRIs. Although it was devoid of these side effects, it was nevertheless found to produce problematic sedation, nausea, dizziness, and visual disturbances. Consequently, nefazodone was never extensively adopted in clinical practice. This fact, as well as reports of rare cases of sometimes fatal
hepatotoxicity, led the original manufacturer to discontinue production of branded nefazodone in 2004. Generic nefazodone remains available in the United States.

Trazodone received Food and Drug Administration (FDA) approval in 1981 as a treatment for major depressive disorder (MDD). Its novel triazolopyridine chemical structure distinguished it from the TCAs, and clinical trials suggested improved safety and tolerability compared with TCAs. There were high expectations that it would replace the older drugs as a mainstay of treatment for depression. However, the extreme sedation associated with trazodone, even at subtherapeutic doses, limited the clinical effectiveness of the drug. However, its soporific properties made trazodone a favorite alternative to standard hypnotics as a sleep-inducing agent. Unlike conventional sleeping pills, trazodone is not a controlled substance.

In 2010, the FDA approved an extended-release, once-daily formulation (Oleptro) as a treatment for MDD in adults. In the trial leading to the approval of the extended-release formulation, the most common adverse events were somnolence or sedation, dizziness, constipation, and blurred vision. Surprisingly, only 4 percent of patients in the trazodone group discontinued treatment because of somnolence or sedation.

**NEFAZODONE**

**Pharmacologic Actions**

Nefazodone is rapidly and completely absorbed but is then extensively metabolized so that the bioavailability of active compounds is about 20 percent of the oral dose. Its half-life is 2 to 4 hours. Steady-state concentrations of nefazodone and its principal active metabolite, hydroxynefazodone, are achieved within 4 to 5 days. Metabolism of nefazodone in elderly persons, especially women, is about half of that seen in younger persons, so lowered doses are recommended for elderly persons. An important metabolite of nefazodone is meta-chlorophenylpiperazine (mCPP), which has some serotonergic effects and may cause migraine, anxiety, and weight loss.

Although nefazodone is an inhibitor of serotonin uptake and, more weakly, of norepinephrine reuptake, its antagonism of serotonin 5-HT$_A$ receptors is thought to produce its antianxiety and antidepressant effects. Nefazodone is also a mild antagonist of the $\alpha_1$-adrenergic receptors, which predisposes some persons to orthostatic hypotension but is not sufficiently potent to produce priapism.

**Therapeutic Indications**

Nefazodone is effective for the treatment of major depression. The usual effective dosage is 300 to 600 mg a day. In direct comparison with SSRIs, nefazodone is less likely to cause inhibition of orgasm or decreased sexual desire. Nefazodone is also effective for treatment of panic disorder and panic with comorbid depression or depressive symptoms, generalized anxiety disorder, and premenstrual dysphoric disorder and for management of chronic pain. It is not effective for the treatment of OCD. Nefazodone
increases rapid eye movement (REM) sleep and increases sleep continuity. Nefazodone is also of use in patients with PTSD and chronic fatigue syndrome. It may also be effective in patients who have been treatment resistant to other antidepressant drugs.

**Precautions and Adverse Reactions**

The most common reasons for discontinuing nefazodone use are sedation, nausea, dizziness, insomnia, weakness, and agitation. Many patients report no specific side effect but describe a vague sense of feeling medicated. Nefazodone also causes visual trails, in which patients see an afterimage when looking at moving objects or when moving their heads quickly.

A major safety concern with the use of nefazodone is severe elevation of hepatic enzymes, and, in some instances, liver failure. Accordingly, serial hepatic function tests need to be done when patients are treated with nefazodone. Hepatic effects can be seen early in treatment and are more likely to develop when nefazodone is combined with other drugs metabolized in the liver.

Some patients taking nefazodone may experience a decrease in blood pressure that can cause episodes of postural hypotension. Nefazodone should therefore be used with caution by persons with underlying cardiac conditions or history of stroke or heart attack, dehydration, or hypovolemia or by persons being treated with antihypertensive medications. Patients switched from SSRIs to nefazodone may experience an increase in side effects, possibly because nefazodone does not protect against SSRI withdrawal symptoms. One of its metabolites, mCPP, may actually intensify these discontinuation symptoms. Patients have survived nefazodone overdoses in excess of 10 g, but deaths have been reported when it has been combined with alcohol. Nausea, vomiting, and somnolence are the most common signs of toxicity.

The effects of nefazodone in human mothers are not as well understood as those of the SSRIs, mainly because of the paucity of its clinical use. Nefazodone should therefore be used during pregnancy only if the potential benefit to the mother outweighs the potential risks to the fetus. It is not known whether nefazodone is excreted in human breast milk. Therefore, it should be used with caution by lactating mothers. The nefazodone dosage should be lowered in persons with severe hepatic disease, but no adjustment is necessary for persons with renal disease (Table 29.23-1).

| Table 29.23-1 | Adverse Reactions Reported with Nefazodone (300–600 mg a Day) |
Drug Interactions and Laboratory Interferences

Nefazodone should not be given concomitantly with MAOIs. In addition, nefazodone has particular drug–drug interactions with the triazolobenzodiazepines triazolam (Halcion) and alprazolam (Xanax) because of the inhibition of CYP3A4 by nefazodone. Potentially elevated levels of each of these drugs can develop after administration of nefazodone, but the levels of nefazodone are generally not affected. The dose of triazolam should be lowered by 75 percent, and the dose of alprazolam should be lowered by 50 percent when given concomitantly with nefazodone.

Nefazodone may slow the metabolism of digoxin; therefore, digoxin levels should be monitored carefully in persons taking both medications. Nefazodone also slows the metabolism of haloperidol (Haldol) so that the dosage of haloperidol should be reduced in persons taking both medications. Addition of nefazodone may also exacerbate the adverse effects of lithium carbonate (Eskalith).

There are no known laboratory interferences associated with nefazodone.

Dosage and Clinical Guidelines

Nefazodone is available in 50-, 200-, and 250-mg unscored tablets and 100- and 150-mg scored tablets. The recommended starting dosage of nefazodone is 100 mg twice a day, but 50 mg twice a day may be better tolerated, especially by elderly persons. To limit the development of adverse effects, the dosage should be slowly raised in increments of 100 to 200 mg a day at intervals of no less than 1 week per increase. The optimal dosage is 300 to 600 mg daily in two divided doses. However, some studies report that nefazodone is effective when taken once a day, especially at bedtime. Geriatric persons should receive dosages about two-thirds of the usual nongeriatric dosages, with a maximum of 400 mg a day. Similar to other antidepressants, clinical benefit of nefazodone usually appears after 2 to 4 weeks of treatment. Patients with premenstrual syndrome are treated with a flexible dosage that averages about 250 mg a day.

TRAZODONE
Pharmacologic Actions

Trazodone is readily absorbed from the GI tract and reaches peak plasma levels in about 1 hour. It has a half-life of 5 to 9 hours. Trazodone is metabolized in the liver, and 75 percent of its metabolites are excreted in the urine.

Trazodone is a weak inhibitor of serotonin reuptake and a potent antagonist of serotonin 5-HT$_{2A}$ and 5-HT$_{2C}$ receptors. The active metabolite of trazodone is mCPP, which is an agonist at 5-HT$_{2C}$ receptors and has a half-life of 14 hours. mCPP has been associated with migraine, anxiety, and weight loss. The adverse effects of trazodone are partially mediated by α$_{1}$-adrenergic receptor antagonism.

Therapeutic Indications

Depressive Disorders. The main indication for the use of trazodone is MDD. There is a clear dose–response relationship, with dosages of 250 to 600 mg a day being necessary for trazodone to have therapeutic benefit. Trazodone increases total sleep time, decreases the number and the duration of nighttime awakenings, and decreases the amount of REM sleep. Unlike tricyclic drugs, trazodone does not decrease stage 4 sleep. Trazodone is thus useful for depressed persons with anxiety and insomnia.

Insomnia. Trazodone is a first-line agent for the treatment of insomnia because of its marked sedative qualities and favorable effects on sleep architecture (see above) combined with its lack of anticholinergic effects. Trazodone is effective for insomnia caused by depression or use of drugs. When used as a hypnotic, the usual initial dosage is 25 to 100 mg at bedtime.

Erectile Disorder. Trazodone is associated with an increased risk of priapism. Trazodone can potentiate erections resulting from sexual stimulation. It has thus been used to prolong erectile time and turgidity in some men with erectile disorder. The dosage for this indication is 150 to 200 mg a day. Trazodone-triggered priapism (an erection lasting more than 3 hours with pain) is a medical emergency. The use of trazodone for treatment of male erectile dysfunction has diminished considerably since the introduction of phosphodiesterase (PDE)-5 agents (see Chapter 25).

Other Indications. Trazodone may be useful in low dosages (50 mg a day) for controlling severe agitation in children with developmental disabilities and elderly persons with dementia. At dosages above 250 mg a day, trazodone reduces the tension and apprehension associated with generalized anxiety disorder. It has been used to treat depression in patients with schizophrenia. Trazodone may have a beneficial effect on insomnia and nightmares in persons with PTSD.

Precautions and Adverse Reactions
The most common adverse effects associated with trazodone are sedation, orthostatic hypotension, dizziness, headache, and nausea. Some persons experience dry mouth or gastric irritation. The drug is not associated with anticholinergic adverse effects, such as urinary retention, weight gain, and constipation. A few case reports have noted an association between trazodone and arrhythmias in persons with preexisting premature ventricular contractions or mitral valve prolapse. Neutropenia, usually not of clinical significance, may develop, which should be considered if persons have fever or sore throat.

Trazodone may cause significant orthostatic hypotension 4 to 6 hours after a dose is taken, especially if taken concurrently with antihypertensive agents or if a large dose is taken without food. Administration of trazodone with food slows absorption and reduces the peak plasma concentration, thus reducing the risk of orthostatic hypotension.

Because suicide attempts often involve ingestion of sleeping pills, it is important to be familiar with the symptoms and treatment of trazodone overdose. Patients have survived trazodone overdoses of more than 9 g. Symptoms of overdose include lethargy, vomiting, drowsiness, headache, orthostasis, dizziness, dyspnea, tinnitus, myalgias, tachycardia, incontinence, shivering, and coma. Treatment consists of emesis or lavage and supportive care. Forced diuresis may enhance elimination. Treat hypotension and sedation as appropriate.

Trazodone causes priapism, prolonged erection in the absence of sexual stimuli, in one of every 10,000 men. Trazodone-induced priapism usually appears in the first 4 weeks of treatment but may occur as late as 18 months into treatment. It can appear at any dose. In such cases, trazodone use should be discontinued, and another antidepressant should be used. Painful erections or erections lasting more than 1 hour are warning signs that warrant immediate discontinuation of the drug and medical evaluation. The first step in the emergency management of priapism is intracavernosal injection of an α₁-adrenergic agonist pressor agent, such as metaraminol (Aramine) or epinephrine. In about one-third of reported cases, surgical intervention was required. In some cases, permanent impairment of erectile function or impotence resulted.

The use of trazodone is contraindicated in pregnant and nursing women. Trazodone should be used with caution in persons with hepatic and renal diseases.

**Drug Interactions**

Trazodone potentiates the CNS depressant effects of other centrally acting drugs and alcohol. Concurrent use of trazodone and antihypertensives may cause hypotension. No cases of hypertensive crisis have been reported when trazodone has been used to treat MAOI-associated insomnia. Trazodone can increase levels of digoxin and phenytoin. Trazodone should be used with caution in combination with warfarin. Drugs that inhibit CYP3A4 can increase levels of trazodone’s major metabolite, mCPP, leading to an increase in side effects.

**Laboratory Interferences**
Dosage and Clinical Guidelines

Trazodone is available in 50-, 100-, 150-, and 300-mg tablets. Once-a-day dosing is as effective as divided dosing and reduces daytime sedation. The usual starting dose is 50 mg before sleep. The dosage can be increased in increments of 50 mg every 3 days if sedation or orthostatic hypotension does not become a problem. The therapeutic range for trazodone is 200 to 600 mg a day in divided doses. Some reports indicate that dosages of 400 to 600 mg a day are required for maximal therapeutic effects; other reports indicate that 250 to 400 mg a day is sufficient. The dosage may be titrated up to 300 mg a day; then the person can be evaluated for the need for further dosage increases on the basis of the presence or the absence of signs of clinical improvement.

Once-daily trazodone is available as bisectable tablets of 150 mg or 300 mg. The starting dosage of the extended-release formulation is 150 mg once daily. It may be increased by 75 mg per day every 3 days. The maximum dosage is 375 mg per day. Dosing should be at the same time every day in the late evening, preferably at bedtime, on an empty stomach. Tablets should be swallowed whole or broken in half along the score line.

### 29.24 Opioid Receptor Agonists

Opioid receptor agonists are a structurally diverse group of compounds that are used for pain management. These drugs are also called narcotics. Although highly effective as analgesics, they often cause dependence and are frequently diverted for recreational use. Commonly used opioid agonists for pain relief include morphine, hydromorphone (Dilaudid), codeine, meperidine (Demerol), oxycodone (OxyContin), buprenorphine (Buprenex), hydrocodone (Robidone), tramadol (Ultram), and fentanyl (Durogesic). Heroin is used as a street drug. Methadone is used both for pain management and for treatment of opiate addiction. This chapter focuses on the μ-opioid receptor agonists that are most likely to be used in the treatment of psychiatric disorders instead of pain management.

It is now recognized that the pharmacology of the opioid system is complex. There are multiple types of opioid receptors, with μ- and κ-opioid receptors representing functionally opposing endogenous systems (Table 29.24-1). All of the compounds above, which represent the most extensively used narcotic analgesics, are agonists at μ-opioid receptors. However, analgesic effects also result from antagonist effects on the κ-opioid receptor. Buprenorphine has mixed receptor effects, being primarily a μ-opioid receptor agonist as well as a κ-opioid antagonist.

#### Table 29.24-1

| μ- and κ-Opiate Receptors |
There is growing interest in the use of some drugs that act on opioid receptors as alternative treatments for a subpopulation of patients with refractory depression, as well as treatment for cutting behavior in patients with borderline personality disorder.

Consideration of such off-label use is tempered by the well-known fact that ongoing, regular use of opioids produces dependence and tolerance and may lead to maladaptive use, functional impairment, and withdrawal symptoms. The prevalence of opioid use, abuse, and dependence, particularly in regard to prescription opioids, has risen in recent years.

Before using opioid receptor agonists with patients who have failed on multiple conventional therapeutic agents, screen carefully for history of drug abuse, document the rationale for off-label use, establish treatment ground rules, obtain written consent, consult with primary care physician, and monitor closely. Avoid replacing “lost” prescriptions and providing early prescription renewals.

**PHARMACOLOGIC ACTIONS**

Methadone and buprenorphine are absorbed rapidly from the GI tract. Hepatic first-pass metabolism significantly affects the bioavailability of each of the drugs but in markedly different ways. For methadone, hepatic enzymes reduce the bioavailability of an oral dosage by about half, an effect that is easily managed with dosage adjustments.

For buprenorphine, first-pass intestinal and hepatic metabolism eliminates oral bioavailability almost completely. When used in opioid detoxification, buprenorphine is given sublingually in either a liquid or a tablet formulation.

The peak plasma concentrations of oral methadone are reached within 2 to 6 hours, and the plasma half-life initially is 4 to 6 hours in opioid-naive persons and 24 to 36 hours after steady dosing of any type of opioid. Methadone is highly protein bound and equilibrates widely throughout the body, which ensures little postdosage variation in steady-state plasma concentrations.

Elimination of a sublingual dosage of buprenorphine occurs in two phases: an initial phase with a half-life of 3 to 5 hours and a terminal phase with a half-life of more than 24 hours. Buprenorphine dissociates from its receptor binding site slowly, which permits an every-other-day dosing schedule.

Methadone acts as pure agonists at μ-opioid receptors and has negligible agonist or antagonist activity at κ- or δ-opioid receptors. Buprenorphine is a partial agonist at μ-receptors, a potent antagonist at κ-receptors, and neither an agonist nor an antagonist at δ-receptors.
THERAPEUTIC INDICATIONS

Methadone

Methadone is used for short-term detoxification (7 to 30 days), long-term detoxification (up to 180 days), and maintenance (treatment beyond 180 days) of opioid-dependent individuals. For these purposes, it is only available through designated clinics called methadone maintenance treatment programs (MMTPs) and in hospitals and prisons. Methadone is a schedule II drug, which means that its administration is tightly governed by specific federal laws and regulations.

Enrollment in a methadone program reduces the risk of death by 70 percent; reduces illicit use of opioids and other substances of abuse; reduces criminal activity; reduces the risk of infectious diseases of all types, most importantly HIV and hepatitis B and C infection; and in pregnant women, reduces the risk of fetal and neonatal morbidity and mortality. The use of methadone maintenance frequently requires lifelong treatment.

Some opioid-dependence treatment programs use a stepwise detoxification protocol in which a person addicted to heroin switches first to the strong agonist methadone; then to the weaker agonist buprenorphine; and finally to maintenance on an opioid receptor antagonist, such as naltrexone (ReVia). This approach minimizes the appearance of opioid withdrawal effects, which, if they occur, are mitigated with clonidine (Catapres). However, compliance with opioid receptor antagonist treatment is poor outside of settings using intensive cognitive-behavioral techniques. In contrast, noncompliance with methadone maintenance precipitates opioid withdrawal symptoms, which serve to reinforce the use of methadone and make cognitive-behavioral therapy less than essential. Thus, some well-motivated, socially integrated former heroin addicts are able to use methadone for years without participation in a psychosocial support program.

Data pooled from many reports indicate that methadone is more effective when taken at dosages in excess of 60 mg a day. The analgesic effects of methadone are sometimes used in the management of chronic pain when less addictive agents are ineffective.

Pregnancy. Methadone maintenance, combined with effective psychosocial services and regular obstetric monitoring, significantly improves obstetric and neonatal outcomes for women addicted to heroin. Enrollment of a heroin-addicted pregnant woman in such a maintenance program reduces the risk of malnutrition, infection, preterm labor, spontaneous abortion, preeclampsia, eclampsia, abruptio placenta, and septic thrombophlebitis.

The dosage of methadone during pregnancy should be the lowest effective dosage, and no withdrawal to abstinence should be attempted during pregnancy. Methadone is metabolized more rapidly in the third trimester, which may necessitate higher dosages. To avoid potentially sedating postdose peak plasma concentrations, the daily dose can be administered in two divided doses during the third trimester. Methadone treatment has no known teratogenic effects.
Neonatal Methadone Withdrawal Symptoms. Withdrawal symptoms in newborns frequently include tremor, a high-pitched cry, increased muscle tone and activity, poor sleep and eating, mottling, yawning, perspiration, and skin excoriation. Convulsions that require aggressive anticonvulsant therapy may also occur. Withdrawal symptoms may be delayed in onset and prolonged in neonates because of their immature hepatic metabolism. Women taking methadone are sometimes counseled to initiate breastfeeding as a means of gently weaning their infants from methadone dependence, but they should not breastfeed their babies while still taking methadone.

Buprenorphine

The analgesic effects of buprenorphine are sometimes used in the management of chronic pain when less addictive agents are ineffective. Because buprenorphine is a partial agonist rather than a full agonist at the μ-receptor and is a weak antagonist at the κ-receptor, this agent produces a milder withdrawal syndrome and has a wider margin of safety than the full μ-agonist compounds generally used in treatment. Buprenorphine has a ceiling effect beyond which dose increases prolong the duration of action of the drug without further increasing the agonist effects. Because of this, buprenorphine has a high clinical safety profile, with limited respiratory depression, therefore decreasing the likelihood of lethal overdose. Buprenorphine does have the capacity to cause typical side effects associated with opioids, including sedation, nausea and vomiting, constipation, dizziness, headache, and sweating. A relevant pharmacokinetic consideration when using buprenorphine is the fact that it requires hepatic conversion to become analgesic (N-dealkylation catalyzed by CYP3A4). This may explain why some patients do not benefit from buprenorphine. Genetics, grapefruit juice, and many medications (including fluoxetine and fluvoxamine) can reduce a person’s ability to metabolize buprenorphine into its bioactive form.

To reduce the likelihood of abusing buprenorphine via the IV route, buprenorphine has been combined with the narcotic antagonist naloxone for sublingual administration. Because naloxone is poorly absorbed by the sublingual route, when the combination drug is taken sublingually, there is no effect of the naloxone on the efficacy of buprenorphine. If an opioid-dependent individual injects the combination medication, the naloxone precipitates a withdrawal reaction, therefore reducing the likelihood of illicit injection use of the sublingual preparation.

Inducting and stabilizing a patient on buprenorphine is analogous to inducing and stabilizing a patient on methadone except that, as a partial agonist, buprenorphine has the potential to cause precipitated withdrawal in patients who have recently taken full agonist opioids. Thus, a patient must abstain from the use of short-acting opioids for 12 to 24 hours before starting buprenorphine and from longer acting opioids such as methadone for 24 to 48 hours or longer. The physician must assess the patient clinically and determine that the patient is in mild to moderate opioid withdrawal with objectively observable withdrawal signs before initiating buprenorphine.

In most instances, a relatively low dose of buprenorphine (2 to 4 mg) can then be
administered with additional doses given in 1 to 2 hours if withdrawal signs persist. The goal for the first 24 hours is to suppress withdrawal signs and symptoms, and the total 24-hour dose to do so can range from 2 to 16 mg on the first day. In subsequent days, the dose can be adjusted upward or downward to resolve withdrawal fully and, as with methadone, to achieve an absence of craving, adequate tolerance to prevent reinforcement from the use of other opioids, and ultimately abstinence from other opioids while minimizing side effects. Dose-ranging studies have demonstrated that dosages of 6 to 16 mg per day are associated with improved treatment outcomes compared with lower doses of buprenorphine (1 to 4 mg). Sometimes patients seem to need dosages higher than 16 mg per day, although there is no evidence for any benefit of dosages beyond 32 mg per day. For the treatment of opioid dependence, a dose of approximately 4 mg of sublingual buprenorphine is the equivalent of a daily dose of 40 mg of oral methadone. It has also been demonstrated that daily, alternate-day, or three-times-per-week administration has equivalent effects in suppressing the symptoms of opioid withdrawal in dependent individuals. The combination tablet is recommended for most clinical purposes, including induction and maintenance. The buprenorphine mono should be used only for pregnant patients or for patients who have a documented anaphylactic reaction to naloxone.

Newer forms of buprenorphine delivery, including a transdermal skin patch, a long-acting depot intramuscular injection that provides therapeutic plasma levels for several weeks, and subcutaneous buprenorphine implants that may provide therapeutic plasma levels for 6 months, are being investigated. The last two delivery systems could obviate the need for taking medications daily while virtually eliminating the risk of medication nonadherence.

Tramadol

There are multiple reports of tramadol’s antidepressant effects, both as monotherapy and augmentation agent in treatment-resistant depression. Clinical and experimental data suggest that tramadol has an inherent antidepressant-like activity. Tramadol has a complex pharmacology. It is a weak μ-opioid receptor agonist, a 5-HT releasing agent, a DA-releasing agent, a 5-HT\textsubscript{2C} receptor antagonist, an norepinephrine reuptake inhibitor, an N-methyl-D-aspartate (NMDA) receptor antagonist, a nicotinic acetylcholine receptor antagonist, a TRPV1 receptor agonist and an M1 and M3 muscarinic acetylcholine receptor antagonist. Consistent with the evidence of its antidepressant effects is the fact that tramadol has a close structural similarity to the antidepressant venlafaxine.

Both venlafaxine and tramadol inhibit norepinephrine/serotonin reuptake and inhibit the reserpine-induced syndrome completely. Both compounds also have an analgesic effect on chronic pain. Venlafaxine may have an opioid component, and naloxone reverses the antipain effect of venlafaxine. Nonopioid activity is demonstrated by the fact that its analgesic effect is not fully antagonized by the μ-opioid receptor antagonist naloxone. Indicative of their structural similarities, venlafaxine may cause false-positive results on liquid chromatography tests to detect urinary tramadol levels.
Another relevant property of tramadol is its relatively long half-life, which reduces the potential for misuse. Its habituating effects are found to be much less than other opiate agonists, but abuse, withdrawal, and dependence are risks. Tramadol requires metabolism to become analgesic: individuals who are CYP2D6 “poor metabolizers” or use drugs that are CYP2D6 inhibitors reduce the efficacy of tramadol (the same is true of codeine).

PRECAUTIONS AND ADVERSE REACTIONS

The most common adverse effects of opioid receptor agonists are lightheadedness, dizziness, sedation, nausea, constipation, vomiting, perspiration, weight gain, decreased libido, inhibition of orgasm, and insomnia or sleep irregularities. Opioid receptor agonists are capable of inducing tolerance as well as producing physiologic and psychological dependence. Other CNS adverse effects include depression, sedation, euphoria, dysphoria, agitation, and seizures. Delirium has been reported in rare cases. Occasional non-CNS adverse effects include peripheral edema, urinary retention, rash, arthralgia, dry mouth, anorexia, biliary tract spasm, bradycardia, hypotension, hypoventilation, syncope, antidiuretic hormone–like activity, pruritus, urticaria, and visual disturbances. Menstrual irregularities are common in women, especially in the first 6 months of use. Various abnormal endocrine laboratory indexes of little clinical significance may also be seen.

Most persons develop tolerance to the pharmacologic adverse effects of opioid agonists during long-term maintenance, and relatively few adverse effects are experienced after the induction period.

Overdosage

The acute effects of opioid receptor agonist overdosage include sedation, hypotension, bradycardia, hypothermia, respiratory suppression, miosis, and decreased GI motility. Severe effects include coma, cardiac arrest, shock, and death. The risk of overdosage is greatest in the induction stage of treatment and in persons with slow drug metabolism caused by preexisting hepatic insufficiency. Deaths have been caused during the first week of induction by methadone dosages of only 50 to 60 mg a day.

The risk of overdosage with buprenorphine appears to be lower than with methadone. However, deaths have been caused by use of buprenorphine in combination with benzodiazepines.

Withdrawal Symptoms

Abrupt cessation of methadone use triggers withdrawal symptoms within 3 to 4 days, which usually reach peak intensity on the sixth day. Withdrawal symptoms include weakness, anxiety, anorexia, insomnia, gastric distress, headache, sweating, and hot and cold flashes. The withdrawal symptoms usually resolve after 2 weeks. However, a protracted methadone abstinence syndrome is possible that may include restlessness and...
The withdrawal symptoms associated with buprenorphine are similar to, but less marked than, those caused by methadone. In particular, buprenorphine is sometimes used to ease the transition from methadone to opioid receptor antagonists or abstinence because of the relatively mild withdrawal reaction associated with discontinuation of buprenorphine.

**DRUG–DRUG INTERACTIONS**

Opioid receptor agonists can potentiate the CNS-depressant effects of alcohol, barbiturates, benzodiazepines, other opioids, low-potency dopamine receptor antagonists, tricyclic and tetracyclic drugs, and MAOIs. Carbamazepine (Tegretol), phenytoin (Dilantin), barbiturates, rifampin (Rimactane, Rifadin), and heavy long-term consumption of alcohol may induce hepatic enzymes, which may lower the plasma concentration of methadone or buprenorphine and thereby precipitate withdrawal symptoms. In contrast, however, hepatic enzyme induction may increase the plasma concentration of active levomethadyl metabolites and cause toxicity.

Acute opioid withdrawal symptoms may be precipitated in persons on methadone maintenance therapy who take pure opioid receptor antagonists such as naltrexone, nalmefene (Revex), and naloxone (Narcan); partial agonists such as buprenorphine; or mixed agonist–antagonists such as pentazocine (Talwin). These symptoms may be mitigated by use of clonidine, a benzodiazepine, or both.

Competitive inhibition of methadone or buprenorphine metabolism after short-term use of alcohol or administration of cimetidine (Tagamet), erythromycin, ketoconazole (Nizoral), fluoxetine (Prozac), fluvoxamine (Luvox), loratadine (Claritin), quinidine (Quinidex), and alprazolam (Xanax) may lead to higher plasma concentrations or a prolonged duration of action of methadone or buprenorphine. Medications that alkalinize the urine may reduce methadone excretion.

Methadone maintenance may also increase plasma concentrations of desipramine (Norpramin, Pertofrane) and fluvoxamine. Use of methadone may increase zidovudine (Retrovir) concentrations, which increases the possibility of zidovudine toxicity at otherwise standard dosages. Moreover, in vitro human liver microsome studies demonstrate competitive inhibition of methadone demethylation by several protease inhibitors, including ritonavir (Norvir), indinavir (Crixivan), and saquinavir (Invirase). The clinical relevance of this finding is unknown.

Fatal drug–drug interactions with the MAOIs are associated with use of the opioids fentanyl (Sublimaze) and meperidine (Demerol) but not with use of methadone, levomethadyl, or buprenorphine.

Tramadol may interact with drugs that inhibit serotonin reuptake. Such combinations can trigger seizures and serotonin syndrome. These events may also develop during tramadol monotherapy, either at routine or excessive doses. Risk of interactions is increased when tramadol is combined with virtually all classes of antidepressants and with drugs that lower the seizure threshold, especially the antidepressant bupropion.
LABORATORY INTERFERENCES

Methadone and buprenorphine can be tested for separately in urine toxicology to distinguish them from other opioids. No known laboratory interferences are associated with the use of methadone or buprenorphine.

DOSAGE AND CLINICAL GUIDELINES

Methadone

Methadone is supplied in 5-, 10-, and 40-mg dispersible scored tablets; 40-mg scored wafers; 5-mg/5-mL, 10-mg/5-mL, and 10-mg/mL solutions; and a 10-mg/mL parenteral form. In maintenance programs, methadone is usually dissolved in water or juice, and dose administration is directly observed to ensure compliance. For induction of opioid detoxification, an initial methadone dose of 15 to 20 mg will usually suppress craving and withdrawal symptoms. However, some individuals may require up to 40 mg a day in single or divided doses. Higher dosages should be avoided during induction of treatment to reduce the risk of acute toxicity from overdosage.

Over several weeks, the dosage should be raised to at least 70 mg a day. The maximum dosage is usually 120 mg a day, and higher dosages require prior approval from regulatory agencies. Dosages above 60 mg a day are associated with much more complete abstinence from use of illicit opioids than are dosages less than 60 mg a day.

The duration of treatment should not be predetermined but should be based on response to treatment and assessment of psychosocial factors. All studies of methadone maintenance programs endorse long-term treatment (i.e., several years) as more effective than short-term programs (i.e., less than 1 year) for prevention of relapse into opioid abuse. In actual practice, however, a minority of programs are permitted by policy or approved by insurers to provide even 6 months of continuous maintenance treatment. Moreover, some programs actually encourage withdrawal from methadone in less than 6 months after induction. This is quite ill conceived because more than 80 percent of persons who terminate methadone maintenance treatment eventually return to illicit drug use within 2 years. In programs that offer both maintenance and withdrawal treatments, the overwhelming majority of participants enroll in the maintenance treatment.

Buprenorphine

Buprenorphine is supplied as a 0.3-mg/mL solution in 1-mL ampules. Sublingual tablet formulations of buprenorphine containing buprenorphine only or buprenorphine combined with naloxone in a 4:1 ratio are used for opioid maintenance treatment. Buprenorphine is not used for short-term opioid detoxification. Maintenance dosages of 8 to 16 mg thrice weekly have effectively reduced heroin use. Physicians must be trained and certified to carry out this therapy in their private offices. There are a number of approved training programs in the United States.
Tramadol

There are no controlled trials establishing the appropriate dosing schedule for tramadol when used for conditions other than pain. Tramadol is available in many formulations. These range from capsules (regular and extended release) to tablets (regular, extended release, chewable tablets) that can be taken sublingually, suppositories and injectable ampules. It also comes as tablets and capsules containing acetaminophen or aspirin. Doses in case reports of treatment for depression or OCD range from 50 to 200 mg a day and involve short-term use. The long-term use of tramadol in the treatment of psychiatric disorders has not been studied.

29.25 Opioid Receptor Antagonists: Naltrexone, Nalmefene, and Naloxone

Naltrexone (Revia, Depade) and naloxone (Narcan) are competitive opioid antagonists. They bind to opioid receptors without causing their activation. Because these drugs induce opioid withdrawal effects in people using full opioid agonists, these drugs are classified as opioid antagonists.

Naltrexone is the most widely used of these drugs. It has a relatively long half-life, is orally effective, is not associated with dysphoria, and is administered once daily. Naloxone, which predated naltrexone to treat narcotic overdose, became less widely used for preventing relapse to opiate use in detoxified opiate addicts. Since its introduction, naltrexone has been tried for the treatment of a wide range of psychiatric disorders, including, among others, eating disorders, autism, self-injurious behavior, cocaine dependence, gambling, and alcoholism. Naltrexone was approved for the treatment of alcohol dependence in 1994. A number of generic formulations are also available. An extended-release, once-a-month injectable suspension (Vivitrol) was also approved in 2006. Nalmefene (Revex) is indicated for the complete or partial reversal of opioid drug effects and in the management of known or suspected opioid overdose. An oral formulation of nalmefene is available in some countries but not in the United States. Nalmefene (Revex) is an opioid receptor antagonist that is sometimes used in the management of alcohol dependence.

PHARMACOLOGICAL ACTIONS

Oral opioid receptor antagonists are rapidly absorbed from the gastrointestinal (GI) tract, but because of first-pass hepatic metabolism, only 60 percent of a dose of naltrexone and 40 to 50 percent of a dose of nalmefene reach the systemic circulation unchanged. Peak concentrations of naltrexone and its active metabolite, 6-β-naltrexol, are achieved within 1 hour of ingestion. The half-life of naltrexone is 1 to 3 hours and the half-life of 6-β-naltrexol is 13 hours. Peak concentrations of nalmefene are achieved in about 1 to 2 hours, and the half-life is 8 to 10 hours. Clinically, a single dose of naltrexone effectively blocks the rewarding effects of opioids for 72 hours. Traces of 6-β-naltrexol may linger for up to 125 hours after a single dose.

Naltrexone and nalmefene are competitive antagonists of opioid receptors. Understanding the pharmacology of opioid receptors can explain the difference in
adverse effects caused by naltrexone and nalmefene. Opioid receptors in the body are
typed pharmacologically as \( \mu \), \( \kappa \), or \( \delta \). Whereas activation of the \( \kappa \)- and \( \delta \)-receptors is thought to reinforce opioid and alcohol consumption centrally, activation of \( \mu \)-receptors is more closely associated with central and peripheral antiemetic effects. Because naltrexone is a relatively weak antagonist of \( \kappa \)- and \( \delta \)-receptors and a potent \( \mu \)-receptor antagonist, dosages of naltrexone that effectively reduce opioid and alcohol consumption also strongly block \( \mu \)-receptors and therefore may cause nausea. Nalmefene, in contrast, is an equally potent antagonist of all three opioid receptor types, and dosages of nalmefene that effectively reduce opioid and alcohol consumption have no particularly increased effect on \( \mu \)-receptors. Thus, nalmefene is associated clinically with few GI adverse effects.

Naloxone has the highest affinity for the \( \mu \)-receptor but is a competitive antagonist at the \( \mu \)-, \( \kappa \)-, and \( \delta \)-receptors.

Whereas the effects of opioid receptor antagonists on opioid use are easily understood in terms of competitive inhibition of opioid receptors, the effects of opioid receptor antagonists on alcohol dependence are less straightforward and probably relate to the fact that the desire for and the effects of alcohol consumption appear to be regulated by several neurotransmitter systems, both opioid and nonopioid.

**THERAPEUTIC INDICATIONS**

The combination of a cognitive-behavioral program plus use of opioid receptor antagonists is more successful than either the cognitive-behavioral program or use of opioid receptor antagonists alone. Naltrexone is used as a screening test to ensure that the patient is opioid-free before the induction of therapy with naltrexone (see “Naloxone Challenge Test” in Table 29.25-1).

<table>

<th>Table 29.25-1</th>
</tr>
</thead>
<tbody>
<tr>
<td>Naloxone (Narcan) Challenge Test</td>
</tr>
</tbody>
</table>
Patients in detoxification programs are usually weaned from potent opioid agonists such as heroin over a period of days to weeks, during which emergent adrenergic withdrawal effects are treated as needed with clonidine (Catapres). A serial protocol is sometimes used in which potent agonists are gradually replaced by weaker agonists followed by mixed agonist–antagonists and then finally by pure antagonists. For example, an abuser of the potent agonist heroin would switch first to the weaker agonist methadone (Dolophine), then to the partial agonist buprenorphine (Buprenex) or levomethadyl acetate (ORLAAM)—commonly called LAAM—and finally, after a 7- to 10-day washout period, to a pure antagonist, such as naltrexone or nalmefene. However, even with gradual detoxification, some persons continue to experience mild adverse effects or opioid withdrawal symptoms for the first several weeks of treatment with naltrexone.

As the opioid receptor agonist potency diminishes, so do the adverse consequences of discontinuing the drug. Thus, because there are no pharmacological barriers to discontinuation of pure opioid receptor antagonists, the social environment and frequent cognitive-behavioral intervention become extremely important factors supporting continued opioid abstinence. Because of poorly tolerated adverse symptoms, most persons not simultaneously enrolled in a cognitive-behavioral program stop taking opioid receptor antagonists within 3 months. Compliance with the administration of an...
opioid receptor antagonist regimen can also be increased with participation in a well-conceived voucher program.

Issues of medication compliance should be a central focus of treatment. If a person with a history of opioid addiction stops taking a pure opioid receptor antagonist, the person’s risk of relapse into opioid abuse is exceedingly high because reintroduction of a potent opioid agonist would yield a very rewarding subjective “high.” In contrast, compliant persons do not develop tolerance to the therapeutic benefits of naltrexone even if it is administered continuously for 1 year or longer. Individuals may undergo several relapses and remissions before achieving long-term abstinence.

Persons taking opioid receptor antagonists should also be warned that sufficiently high dosages of opioid agonists can overcome the receptor antagonism of naltrexone or nalmefene, which may lead to hazardous and unpredictable levels of receptor activation (see “Precautions and Adverse Reactions”).

Rapid Detoxification
To avoid the 7- to 10-day period of opioid abstinence generally recommended before use of opioid receptor antagonists, rapid detoxification protocols have been developed. Continuous administration of adjunct clonidine—to reduce the adrenergic withdrawal symptoms—and adjunct benzodiazepines, such as oxazepam (Serax)—to reduce muscle spasms and insomnia—can permit use of oral opioid receptor antagonists on the first day of opioid cessation. Detoxification can thus be completed within 48 to 72 hours, at which point opioid receptor antagonist maintenance is initiated. Moderately severe withdrawal symptoms may be experienced on the first day, but they taper off rapidly thereafter.

Because of the potential hypotensive effects of clonidine, the blood pressure (BP) of persons undergoing rapid detoxification must be closely monitored for the first 8 hours. Outpatient rapid detoxification settings must therefore be adequately prepared to administer emergency care.

The main advantage of rapid detoxification is that the transition from opioid abuse to maintenance treatment occurs over just 2 or 3 days. The completion of detoxification in as little time as possible minimizes the risk that the person will relapse into opioid abuse during the detoxification protocol.

Alcohol Dependence
Opioid receptor antagonists are also used as adjuncts to cognitive-behavioral programs for treatment of alcohol dependence. Opioid receptor antagonists reduce alcohol craving and alcohol consumption, and they ameliorate the severity of relapses. The risk of relapse into heavy consumption of alcohol attributable to an effective cognitive-behavioral program alone may be halved with concomitant use of opioid receptor antagonists.

The newer agent nalmefene has a number of potential pharmacological and clinical advantages over its predecessor naltrexone for treatment of alcohol dependence.
Whereas naltrexone may cause reversible transaminase elevations in persons who take dosages of 300 mg a day (which is six times the recommended dosage for treatment of alcohol and opioid dependence [50 mg a day]), nalmefene has not been associated with any hepatotoxicity. Clinically effective dosages of naltrexone are discontinued by 10 to 15 percent of persons because of adverse effects, most commonly nausea. In contrast, discontinuation of nalmefene because of an adverse event is rare at the clinically effective dosage of 20 mg a day and in the range of 10 percent at excessive dosages—that is, 80 mg a day. Because of its pharmacokinetic profile, a given dosage of nalmefene may also produce a more sustained opioid antagonist effect than does naltrexone.

The efficacy of opioid receptor antagonists in reducing alcohol craving may be augmented with a selective serotonin reuptake inhibitor, although data from large trials are needed to assess this potential synergistic effect more fully.

**PRECAUTIONS AND ADVERSE REACTIONS**

Because opioid receptor antagonists are used to maintain a drug-free state after opioid detoxification, great care must be taken to ensure that an adequate washout period elapses—at least 5 days for a short-acting opioid such as heroin and at least 10 days for longer-acting opioids such as methadone—after the last dose of opioids and before the first dose of an opioid receptor antagonist is taken. The opioid-free state should be determined by self-report and urine toxicology screens. If any question persists of whether opioids are in the body despite a negative urine screen result, then a *naloxone challenge test* should be performed. Naloxone challenge is used because its opioid antagonism lasts less than 1 hour, but those of naltrexone and nalmefene may persist for more than 24 hours. Thus, any withdrawal effects elicited by naloxone will be relatively short lived (see “Dosage and Clinical Guidelines”). Symptoms of acute opioid withdrawal include drug craving, feeling of temperature change, musculoskeletal pain, and GI distress. Signs of opioid withdrawal include confusion, drowsiness, vomiting, and diarrhea. Naltrexone and nalmefene should not be taken if naloxone infusion causes any signs of opioid withdrawal except as part of a supervised rapid detoxification protocol.

A set of adverse effects resembling a vestigial withdrawal syndrome tends to affect up to 10 percent of persons who take opioid receptor antagonists. Up to 15 percent of persons taking naltrexone may experience abdominal pain, cramps, nausea, and vomiting, which may be limited by transiently halving the dosage or altering the time of administration. Adverse central nervous system effects of naltrexone, experienced by up to 10 percent of persons, include headache, low energy, insomnia, anxiety, and nervousness. Joint and muscle pains may occur in up to 10 percent of persons taking naltrexone, as may rash.

Naltrexone may cause dosage-related hepatic toxicity at dosages well in excess of 50 mg a day; 20 percent of persons taking 300 mg a day of naltrexone may experience serum aminotransferase concentrations 3 to 19 times the upper limit of normal. The hepatocellular injury of naltrexone appears to be a dose-related toxic effect rather than
an idiosyncratic reaction. At the lowest dosages of naltrexone required for effective opioid antagonism, hepatocellular injury is not typically observed. However, naltrexone dosages as low as 50 mg a day may be hepatotoxic in persons with underlying liver disease, such as persons with cirrhosis of the liver caused by chronic alcohol abuse. Serum aminotransferase concentrations should be monitored monthly for the first 6 months of naltrexone therapy and thereafter on the basis of clinical suspicion. Hepatic enzyme concentrations usually return to normal after discontinuation of naltrexone therapy.

If analgesia is required while a dose of an opioid receptor antagonist is pharmacologically active, opioid agonists should be avoided in favor of benzodiazepines or other nonopioid analgesics. Persons taking opioid receptor antagonists should be instructed that low dosages of opioids will have no effect but larger dosages could overcome the receptor blockade and suddenly produce symptoms of profound opioid overdosage, with sedation possibly progressing to coma or death. Use of opioid receptor antagonists is contraindicated in persons who are taking opioid agonists, small amounts of which may be present in over-the-counter antiemetic and antitussive preparations; in persons with acute hepatitis or hepatic failure; and in persons who are hypersensitive to the drugs.

Because naltrexone is transported across the placenta, opioid receptor antagonists should only be taken by pregnant women if a compelling need outweighs the potential risks to the fetus. It is not known whether opioid receptor antagonists are distributed into breast milk.

Opioid receptor antagonists are relatively safe drugs, and ingestion of high doses of opioid receptor antagonists should be treated with supportive measures combined with efforts to decrease GI absorption.

Because buprenorphine has a high affinity and slow displacement from the opioid receptors, nalmefene may not completely reverse buprenorphine-induced respiratory depression.

**DRUG INTERACTIONS**

Many drug interactions involving opioid receptor antagonists have been discussed earlier, including those with opioid agonists associated with drug abuse as well as those involving antiemetics and antitussives. Because of its extensive hepatic metabolism, naltrexone may affect or be affected by other drugs that influence hepatic enzyme levels. However, the clinical importance of these potential interactions is not known.

One potentially hepatotoxic drug that has been used in some cases with opioid receptor antagonists is disulfiram (Antabuse). Although no adverse effects were observed, frequent laboratory monitoring is indicated when such combination therapy is contemplated. Opioid receptor antagonists have been reported to potentiate the sedation associated with use of thioridazine (Mellaril), an interaction that probably applies equally to all low-potency dopamine receptor antagonists.

Intravenous nalmefene has been administered after benzodiazepines, inhalational
anesthetics, muscle relaxants, and muscle relaxant antagonists administered in conjunction with general anesthetics without any adverse reactions. Care should be taken when using flumazenil (Romazicon) and nalmefene together because both of these agents have been shown to induce seizures in preclinical studies.

LABORATORY INTERFERENCES

The potential for a false-positive urine for opiates using less specific urine screens such as enzyme-multiplied immunoassay technique (EMIT) may exist, given that naltrexone and nalmefene are derivatives of oxymorphone. Thin-layer, gas–liquid, and high-pressure liquid chromatographic methods used for the detection of opiates in the urine are not interfered with by naltrexone.

DOSAGE AND CLINICAL GUIDELINES

To avoid the possibility of precipitating an acute opioid withdrawal syndrome, several steps should be taken to ensure that the person is opioid free. Within a supervised detoxification setting, at least 5 days should elapse after the last dose of short-acting opioids, such as heroin, hydromorphone (Dilaudid), meperidine (Demerol), or morphine, and at least 10 days should elapse after the last dose of longer-acting opioids, such as methadone, before opioid antagonists are initiated. Briefer periods off opioids have been used in rapid detoxification protocols. To confirm that opioid detoxification is complete, urine toxicological screens should demonstrate no opioid metabolites. However, an individual may have a negative urine opioid screen result, yet still be physically dependent on opioids and thus susceptible to antagonist-induced withdrawal effects. Therefore, after the urine screen result is negative, a naloxone challenge test is recommended unless an adequate period of opioid abstinence can be reliably confirmed by observers (Table 29.25-1).

The initial dosage of naltrexone for treatment of opioid or alcohol dependence is 50 mg a day, which should be achieved through gradual introduction, even when the naloxone challenge test result is negative. Various authorities begin with 5, 10, 12.5, or 25 mg and titrate up to the 50-mg dosage over a period ranging from 1 hour to 2 weeks while constantly monitoring for evidence of opioid withdrawal. When a daily dose of 50 mg is well tolerated, it may be averaged over a week by giving 100 mg on alternate days or 150 mg every third day. Such schedules may increase compliance. The corresponding therapeutic dosage of nalmefene is 20 mg a day divided into two equal doses. Gradual titration of nalmefene to this daily dose is probably a wise strategy, although clinical data on dosage strategies for nalmefene are not yet available.

To maximize compliance, it is recommended that family members directly observe ingestion of each dose. Random urine tests for opioid receptor antagonists and their metabolites as well as for ethanol or opioid metabolites should also be taken. Opioid receptor antagonists should be continued until the person is no longer considered psychologically at risk for relapse into opioid or alcohol abuse. This generally requires at least 6 months but may take longer, particularly if there are external stresses.
Nalmefene is available as a sterile solution for intravenous, intramuscular, and subcutaneous administration in two concentrations, containing 100 μg or 1.0 mg of nalmefene free base per milliliter. The 100 μg/mL concentration contains 110.8 μg of nalmefene hydrochloride and the 1.0 mg/mL concentration contains 1.108 mg of nalmefene hydrochloride per milliliter. Both concentrations contain 9.0 mg of sodium chloride per milliliter and the pH is adjusted to 3.9 with hydrochloric acid. Pharmacodynamic studies have shown that nalmefene has a longer duration of action than naloxone at fully reversing opiate activity.

Rapid Detoxification

Rapid detoxification has been standardized using naltrexone, although nalmefene would be expected to be equally effective with fewer adverse effects. In rapid detoxification protocols, the addicted person stops opioid use abruptly and begins the first opioid-free day by taking clonidine, 0.2 mg, orally every 2 hours for nine doses, to a maximum dose of 1.8 mg, during which time the BP is monitored every 30 to 60 minutes for the first 8 hours. Naltrexone, 12.5 mg, is administered 1 to 3 hours after the first dose of clonidine. To reduce muscle cramps and later insomnia, a short-acting benzodiazepine, such as oxazepam, 30 to 60 mg, is administered simultaneously with the first dose of clonidine, and half of the initial dose is readministered every 4 to 6 hours as needed. The maximum daily dosage of oxazepam should not exceed 180 mg. The person undergoing rapid detoxification should be accompanied home by a reliable escort. On the second day, similar doses of clonidine and the benzodiazepine are administered but with a single dose of naltrexone, 25 mg, taken in the morning. Relatively asymptomatic persons may return home after 3 to 4 hours. Administration of the daily maintenance dose of 50 mg of naltrexone is begun on the third day, and the dosages of clonidine and the benzodiazepine are gradually tapered off over 5 to 10 days.

REFERENCES
Phosphodiesterase (PDE)-5 inhibitors, such as sildenafil (Viagra), which was developed in 1998, revolutionized the treatment of the major sexual dysfunction affecting men—erectile disorder. Two congeners have since come on the market—vardenafil (Levitra) and tadalafil (Cialis). All have a similar method of action and have changed people’s expectations of sexual functioning. Although indicated only for the treatment of male erectile dysfunction, there is anecdotal evidence of these drugs being effective in women. They are also being misused as recreational drugs to enhance sexual performance. These drugs have been used by more than 20 million men around the world.

The development of sildenafil provided important information about the physiology of erection. Sexual stimulation causes the release of the neurotransmitter nitric oxide (NO), which increases the synthesis of cyclic guanosine monophosphate (cGMP), causing smooth muscle relaxation in the corpus cavernosum that allows blood to flow into the penis and results in turgidity and tumescence. The concentration of cGMP is regulated by the enzyme PDE-5, which, when inhibited, allows cGMP to increase and enhance erectile function. Because sexual stimulation is required to cause the release of NO, PDE-5 inhibitors have no effect in the absence of such stimulation, an important point to understand when providing information to patients about their use. The congeners vardenafil and tadalafil work in the same way, by inhibiting PDE-5, thus allowing an increase in cGMP and enhancing the vasodilatory effects of NO. For this reason, these drugs are sometimes referred to as NO enhancers.
PHARMACOLOGICAL ACTIONS

All three substances are fairly rapidly absorbed from the gastrointestinal tract, with maximum plasma concentrations reached in 30 to 120 minutes (median, 60 minutes) in the fasting state. Because it is lipophilic, concomitant ingestion of a high-fat meal delays the rate of absorption by up to 60 minutes and reduces the peak concentration by one quarter. These drugs are principally metabolized by the CYP3A4 system, which may lead to clinically significant drug–drug interactions, not all of which have been documented. Excretion of 80 percent of the dose is via feces, and another 13 percent is eliminated in the urine. Elimination is reduced in persons older than age 65 years, which results in plasma concentrations 40 percent higher than in persons age 18 to 45 years. Elimination is also reduced in the presence of severe renal or hepatic insufficiency.

The mean half-lives of sildenafil and vardenafil are 3 to 4 hours, and that of tadalafil is about 18 hours. Tadalafil can be detected in the bloodstream 5 days after ingestion, and because of its long half-life, it has been marketed as effective for up to 36 hours—the so-called weekend pill. The onset of sildenafil occurs about 30 minutes after ingestion on an empty stomach; tadalafil and vardenafil act somewhat more quickly. Clinicians need to be aware of the important clinical observation that these drugs do not by themselves create an erection. Rather, the mental state of sexual arousal brought on by erotic stimulation must first lead to activity in the penile nerves, which then release NO into the cavernosum, triggering the erectile cascade, the resulting erection being prolonged by the NO enhancers. Thus, full advantage may be taken of a sexually exciting stimulus, but the drug is not a substitute for foreplay and emotional arousal.

THERAPEUTIC INDICATIONS

Erectile dysfunctions have traditionally been classified as organic, psychogenic, or mixed. Over the past 20 years, the prevailing view of the cause of erectile dysfunction has shifted away from psychological causes toward organic causes. The latter include diabetes mellitus, hypertension, hypercholesterolemia, cigarette smoking, peripheral vascular disease, pelvic or spinal cord injury, pelvic or abdominal surgery (especially prostate surgery), multiple sclerosis, peripheral neuropathy, and Parkinson’s disease. Erectile dysfunction is often induced by alcohol, nicotine, and other substances of abuse and by prescription drugs.

These drugs are effective regardless of the baseline severity of erectile dysfunction, race, or age. Among those responding to sildenafil are men with coronary artery disease, hypertension, other cardiac disease, peripheral vascular disease, diabetes mellitus, depression, coronary artery bypass graft surgery, radical prostatectomy, transurethral resection of the prostate, spina bifida, and spinal cord injury, as well as persons taking antidepressants, antipsychotics, antihypertensives, and diuretics. However, the response rate is variable.

Sildenafil has been reported to reverse selective serotonin reuptake inhibitor–induced anorgasmia in men. There are anecdotal reports of sildenafil having a therapeutic effect
on sexual inhibition in women as well.

**PRECAUTIONS AND ADVERSE REACTIONS**

A major potential adverse effect associated with use of these drugs is myocardial infarction (MI). The U.S. Food and Drug Administration (FDA) distinguished the risk of MI caused directly by these drugs from that caused by underlying conditions such as hypertension, atherosclerotic heart disease, diabetes mellitus, and other atherogenic conditions. The FDA concluded that when used according to the approved labeling, the drugs do not by themselves confer an increased risk of death. However, there is increased oxygen demand and stress placed on the cardiac muscle by sexual intercourse. Thus, coronary perfusion may be severely compromised, and cardiac failure may occur as a result. For that reason, any person with a history of MI, stroke, renal failure, hypertension, or diabetes mellitus and any person older than the age of 70 years should discuss plans to use these drugs with an internist or a cardiologist. The cardiac evaluation should specifically address exercise tolerance and the use of nitrates.

Use of PDE-5 inhibitors is contraindicated in persons who are taking organic nitrates in any form. Also, amyl nitrate (poppers), a popular substance of abuse used by homosexual men to enhance the intensity of orgasm, should not be used with any of the erection-enhancing drugs. The combination of organic nitrates and PDE inhibitors can cause a precipitous lowering of blood pressure and can reduce coronary perfusion to the point of causing MI and death.

Adverse effects are dose dependent, occurring at higher rates with higher dosages. The most common adverse effects are headache, flushing, and stomach pain. Other less common adverse effects include nasal congestion, urinary tract infection, abnormal vision (colored tinge [usually blue], increased sensitivity to light, or blurred vision), diarrhea, dizziness, and rash. No cases of priapism were reported in premarketing trials. Supportive management is indicated in cases of overdosage. Tadalafil has been associated with back and muscle pain in about 10 percent of patients.

Recently, there have been 50 reports and 14 verified cases of a serious condition in men taking sildenafil called nonarteritic anterior ischemic optic neuropathy. This is an eye ailment that causes restriction of blood flow to the optic nerve and can result in permanent vision loss. The first symptoms appear within 24 hours after use of sildenafil and include blurred vision and some degree of vision loss. The incidence of this effect is very rare—1 in 1 million. In the reported cases, many patients had preexisting eye problems that may have increased their risk, and many had a history of heart disease and diabetes, which may indicate vulnerability in these men to endothelial damage.

In addition to vision problems, in 2010, a warning of possible hearing loss was reported based on 29 incidents of the problem since introduction of these drugs. Hearing loss usually occurs within hours or days of using the drug and in some cases is both unilateral and temporary.

No data are available on the effects on human fetal growth and development or testicular morphologic or functional changes. However, because these drugs are not
considered an essential treatment, they should not be used during pregnancy.

**TREATMENT OF PRIAPISM**

Phenylephrine (Neo-Synephrine) is the drug of choice and first-line treatment of priapism because the drug has almost pure α-agonist effects and minimal β activity. In short-term priapism (less than 6 hours), especially for drug-induced priapism, intracavernosal injection of phenylephrine can be used to cause detumescence. A mixture of 1 ampule of phenylephrine (1 mL/1,000 μg) should be diluted with an additional 9 mL of normal saline. Using a 29-gauge needle, 0.3 to 0.5 mL should be injected into the corpora cavernosa, with 10 to 15 minutes between injections. Vital signs should be monitored, and compression should be applied to the area of injection to help prevent hematoma formation.

Phenylephrine can also be used orally, 10 to 20 mg every 4 hours as needed, but it may not be as effective or act as rapidly as the injectable route.

**DRUG INTERACTIONS**

The major route of PDE-5 metabolism is through CYP3A4, and the minor route is through CYP2C9. Inducers or inhibitors of these enzymes will therefore affect the plasma concentration and half-life of sildenafil. For example, 800 mg of cimetidine (Tagamet), a nonspecific CYP inhibitor, increases plasma sildenafil concentrations by 56 percent, and erythromycin (E-mycin) increases plasma sildenafil concentrations by 182 percent. Other, stronger inhibitors of CYP3A4 include ketoconazole (Nizoral), itraconazole (Sporanox), and mibebradil (Posicor). In contrast, rifampicin, a CYP3A4 inducer, decreases plasma concentrations of sildenafil.

**LABORATORY INTERFERENCES**

No laboratory interferences have been described.

**DOSAGE AND CLINICAL GUIDELINES**

Sildenafil is available as 25-, 50-, and 100-mg tablets. The recommended dose of sildenafil is 50 mg taken by mouth 1 hour before intercourse. However, sildenafil may take effect within 30 minutes. The duration of the effect is usually 4 hours, but in healthy young men, the effect may persist for 8 to 12 hours. Based on effectiveness and adverse effects, the dose should be titrated between 25 and 100 mg. Sildenafil is recommended for use no more than once a day. The dosing guidelines for use by women, an off-label use, are the same as those for men.

Increased plasma concentrations of sildenafil may occur in persons older than 65 years of age and those with cirrhosis or severe renal impairment or using CYP3A4 inhibitors. A starting dose of 25 mg should be used in these circumstances.

An investigational nasal spray formulation of sildenafil has been developed that acts within 5 to 15 minutes of administration. This formulation is highly water soluble, and it
is rapidly absorbed directly into the bloodstream. Such a formulation would permit more ease of use.

Vardenafil is supplied in 2.5-, 5-, 10-, and 20-mg tablets. The initial dose is usually 10 mg taken with or without food about 1 hour before sexual activity. The dose can be increased to a maximum of 20 mg or decreased to 5 mg based on efficacy and side effects. The maximum dosing frequency is once per day. As with sildenafil, dosages may have to be adjusted in patients with hepatic impairment or in patients using certain CYP3A4 inhibitors. A 10 mg orally disintegrating form of vardenafil (Staxyn) is available. It is placed on the tongue approximately 60 minutes before sexual activity and should not be used more than once a day.

Tadalafil is available in 2.5-, 5-, or 20-mg tablets for oral administration. The recommended dose of tadalafil is 10 mg before sexual activity, which may be increased to 20 mg or decreased to 5 mg depending on efficacy and side effects. Once-a-day use of the 2.5- or 5-mg pill is acceptable for most patients. Similar cautions apply as mentioned earlier in patients with hepatic impairment and in those taking concomitant potent inhibitors of CYP3A4. As with other PDE-5 inhibitors, concomitant use of nitrates in any form is contraindicated.

29.27 Selective Serotonin–Norepinephrine Reuptake Inhibitors

There are currently four serotonin–norepinephrine reuptake inhibitors (SNRIs) approved for use in the United States: venlafaxine (Effexor and Effexor XR), desvenlafaxine succinate (DVS; Pristiq), duloxetine (Cymbalta), and levomilnacipran (Fetzima). A fifth SNRI, milnacipran (Savella), available in other countries as an antidepressant, has U.S. Food and Drug Administration (FDA) approval in the United States as a treatment for fibromyalgia. The term SNRI reflects the belief that the therapeutic effects of these medications are mediated by concomitant blockade of neuronal serotonin (5-HT) and norepinephrine uptake transporters. The SNRIs are also sometimes referred to as dual reuptake inhibitors, a broader functional class of antidepressant medications that includes tricyclic antidepressants (TCAs) such as clomipramine (Anafranil) and, to a lesser extent, imipramine (Tofranil) and amitriptyline (Elavil). What distinguishes the SNRIs from TCAs is their relative lack of affinity for other receptors, especially muscarinic, histaminergic, and the families of α- and β-adrenergic receptors. This distinction is an important one because the SNRIs have a more favorable tolerability profile than the older dual reuptake inhibitors.

VENLAFAXINE AND DESVENLAFAXINE

Therapeutic Indications

Venlafaxine is approved for treatment of four disorders: major depressive disorder, generalized anxiety disorder, social anxiety disorder, and panic disorder. Major depressive disorder is currently the only FDA-approved indication for DVS.

Depression. The FDA does not recognize any class of antidepressant as being more effective than any other. This does not mean that differences do not exist, but no study to date has sufficiently demonstrated such superiority. It has been argued that direct modulation of serotonin and norepinephrine may convey greater antidepressant effects than are exerted by medications that selectively enhance only noradrenergic or serotonergic neurotransmission. This greater therapeutic benefit could result from an acceleration of postsynaptic adaptation to increased neuronal signaling; simultaneous activation of two pathways for intracellular signal transduction; additive effects on the activity of relevant genes such as brain-derived neurotrophic factor; or, quite simply, broader coverage of depressive symptoms. Clinical evidence supporting this hypothesis first emerged in a pair of studies conducted by the Danish University Antidepressant Group, which found an advantage for the dual reuptake inhibitor clomipramine.
compared with the selective serotonin reuptake inhibitors (SSRIs) citalopram (Celexa) and paroxetine (Paxil). Another report, which compared the results of a group of patients prospectively treated with the combination of the TCAs desipramine (Norpramin) and fluoxetine (Prozac) with a historical comparison group treated with desipramine alone, provided additional support. A meta-analysis of 25 inpatient studies comparing the efficacy of TCAs and SSRIs yielded the strongest evidence. Specifically, although the TCAs were found to have a modest overall advantage, superiority versus SSRIs was almost entirely explained by the studies that used the TCAs that are considered to be dual reuptake inhibitors—clomipramine, amitriptyline, and imipramine. Meta-analyses of head-to-head studies suggest that venlafaxine has the potential to induce higher rates of remission in depressed patients than do the SSRIs. This difference of the venlafaxine advantage is about 6 percent. DVS has not been extensively compared with other classes of antidepressants with respect to efficacy.

**Generalized Anxiety Disorder.** The extended-release formulation of venlafaxine is approved for treatment of generalized anxiety disorder. In clinical trials lasting 6 months, dosages of 75 to 225 mg a day were effective in treating insomnia, poor concentration, restlessness, irritability, and excessive muscle tension related to generalized anxiety disorder.

**Social Anxiety Disorder.** The extended-release formulation of venlafaxine is approved for treatment of social anxiety disorder. Its efficacy was established in 12-week studies.

**Other Indications.** Case reports and uncontrolled studies have indicated that venlafaxine may be beneficial in the treatment of obsessive-compulsive disorder, panic disorder, agoraphobia, social phobia, attention-deficit/hyperactivity disorder, and patients with a dual diagnosis of depression and cocaine dependence. It has also been used in chronic pain syndromes with good effect.

**Precautions and Adverse Reactions**

Venlafaxine has a safety and tolerability profile similar to that of the more widely prescribed SSRI class. Nausea is the most frequently reported treatment-emergent adverse effect associated with venlafaxine and DVS therapy. Initiating therapy at lower dosages may also attenuate nausea. When extremely problematic, treatment-induced nausea can be controlled by prescribing a selective 5-HT₃ antagonist or mirtazapine (Remeron).

Venlafaxine and DVS therapy is associated with sexual side effects, predominantly decreased libido and a delay to orgasm or ejaculation. The incidence of these side effects may exceed 30 to 40 percent when there is direct, detailed assessment of sexual function.

Other common side effects include headache, insomnia, somnolence, dry mouth,
dizziness, constipation, asthenia, sweating, and nervousness. Although several side effects are suggestive of anticholinergic effects, these drugs have no affinity for muscarinic or nicotinic receptors. Thus, noradrenergic agonism is likely to be the culprit.

Higher-dose venlafaxine therapy is associated with an increased risk of sustained elevations of blood pressure (BP). Experience with the instant-release (IR) formulation in studies of depressed patients indicated that sustained hypertension was dose related, increasing from 3 to 7 percent at doses of 100 to 300 mg per day and to 13 percent at doses greater than 300 mg per day. In this dataset, venlafaxine therapy did not adversely affect BP control of patients taking antihypertensives and actually lowered mean values of patients with elevated BP readings before therapy. In controlled studies of the extended-release formulation, venlafaxine therapy resulted in only approximately 1 percent greater risk of high BP when compared with placebo. Arbitrarily capping the upper dose of venlafaxine used in these studies thus greatly attenuated concerns about elevated BP. When higher doses of the extended-release formulation are used, however, monitoring of BP is recommended.

Venlafaxine and DVS are commonly associated with a discontinuation syndrome. This syndrome is characterized by the appearance of a constellation of adverse effects during a rapid taper or abrupt cessation, including dizziness, dry mouth, insomnia, nausea, nervousness, sweating, anorexia, diarrhea, somnolence, and sensory disturbances. It is recommended that, whenever possible, a slow taper schedule should be used when longer-term treatment must be stopped. On occasion, substituting a few doses of the sustained-release formulation of fluoxetine may help to bridge this transition.

There were no overdose fatalities in premarketing trials of venlafaxine, although electrocardiographic changes (e.g., prolongation of QT interval, bundle branch block, QRS interval prolongation), tachycardia, bradycardia, hypotension, hypertension, coma, serotonin syndrome, and seizures were reported. Fatal overdoses have been documented subsequently, typically involving venlafaxine ingestion in combination with other drugs, alcohol, or both.

Information concerning use of venlafaxine and DVS by pregnant and nursing women is not available at this time. Venlafaxine and DVS are excreted in breast milk. Clinicians should carefully weigh the risks and benefits of venlafaxine use by pregnant and nursing women.

**Drug Interactions**

Venlafaxine is metabolized in the liver primarily by the CYP2D6 isoenzyme. Because the parent drug and principal metabolite are essentially equipotent, medications that inhibit this isoenzyme usually do not adversely affect therapy. Venlafaxine is itself a relatively weak inhibitor of CYP2D6, although it can increase levels of substrates, such as desipramine or risperidone (Risperdal). In vitro and in vivo studies have shown venlafaxine to cause little or no inhibition of CYP1A2, CYP2C9, CYP2C19, and CYP3A4.

Venlafaxine is contraindicated in patients taking monoamine oxidase inhibitors (MAOIs) because of the risk of a pharmacodynamic interaction (i.e., serotonin
syndrome). An MAOI should not be started for at least 7 days after stopping venlafaxine. Few data are available regarding the combination of venlafaxine with atypical neuroleptics, benzodiazepines, lithium (Eskalith), and anticonvulsants; therefore, clinical judgment should be exercised when combining medications.

**Laboratory Interferences**

Data are not currently available on laboratory interferences with venlafaxine.

**Dosage and Administration**

Venlafaxine is available in 25-, 37.5-, 50-, 75-, and 100-mg tablets and 37.5-, 75-, and 150-mg extended-release capsules. The tablets and the extended-release capsules are equally potent, and persons stabilized with one can switch to an equivalent dosage of the other. Because the immediate-release tablets are rarely used due to their tendency to cause nausea and the need for multiple daily doses, the dosage recommendations that follow refer to use of the extended-release capsules.

In depressed persons, venlafaxine demonstrates a dose–response curve. The initial therapeutic dosage is 75 mg a day given once a day. However, most persons are started at a dosage of 37.5 mg for 4 to 7 days to minimize adverse effects, particularly nausea. A convenient starter kit for the drug contains a 1-week supply of both the 37.5- and 75-mg strengths. If a rapid titration is preferred, the dosage can be raised to 150 mg per day after day 4. As a rule, the dosage can be raised in increments of 75 mg a day every 4 or more days. Although the recommended upper dosage of the extended-release preparation (venlafaxine XR) is 225 mg per day, it is approved by the FDA for use at dosages up to 375 mg a day. The dosage of venlafaxine should be halved in persons with significantly diminished hepatic or renal function. If discontinued, venlafaxine use should be gradually tapered over 2 to 4 weeks to avoid withdrawal symptoms.

There are minor differences in the doses used for major depression, generalized anxiety disorder, and social anxiety disorder. In the treatment of these disorders, for example, a dose–response effect has not been found. In addition, lower mean dosages are typically used, with most patients taking 75 to 150 mg per day.

DVS is available as 50- and 100-mg extended-release tablets. The therapeutic dose for most patients is 50 mg a day. Although some patients may need higher doses, in clinical trials, no greater therapeutic benefit was noted when the dose was increased. At higher doses, adverse event and discontinuation rates were increased.

**DULOXETINE**

**Pharmacological Actions**

Duloxetine is formulated as a delayed-release capsule to reduce the risk of severe nausea associated with the drug. It is well absorbed, but there is a 2-hour delay before absorption begins. Peak plasma concentrations occur 6 hours after ingestion. Food
delays the time to achieve maximum concentrations from 6 to 10 hours and reduces the extent of absorption by about 10 percent. Duloxetine has an elimination half-life of about 12 hours (range, 8 to 17 hours). Steady-state plasma concentrations occur after 3 days. Elimination is mainly through the isozymes CYP2D6 and CYP1A2. Duloxetine undergoes extensive hepatic metabolism to numerous metabolites. About 70 percent of the drug appears in the urine as metabolites and about 20 percent is excreted in the feces. Duloxetine is 90 percent protein bound.

**Therapeutic Indications**

**Depression.** In contrast to venlafaxine, a small number of studies have compared duloxetine with the SSRIs. Although these studies are suggestive of some advantage in efficacy, their findings are limited by the use of fixed, low starting doses of paroxetine and fluoxetine, but dosages of duloxetine in some studies were as high as 120 mg per day. Any inferences on whether duloxetine is superior to the SSRIs in any aspect of treatment for depression thus await more evidence from properly designed trials.

**Neuropathic Pain Associated with Diabetes and Stress Urinary Incontinence.** Duloxetine is the first drug to be approved by the FDA as a treatment for neuropathic pain associated with diabetes. The drug has been studied for its effects on physical symptoms, including pain, in depressed patients, but these effects have not been compared with those seen with other widely used agents such as venlafaxine and the TCAs. Duloxetine is currently awaiting approval as a treatment for stress urinary incontinence, the inability to voluntarily control bladder voiding, which is the most frequent type of incontinence in women. The action of duloxetine in the treatment of stress urinary incontinence is associated with its effects in the sacral spinal cord, which in turn increase the activity of the striated urethral sphincter. Duloxetine will be marketed under the name Yentreve for this indication.

**Precautions and Adverse Reactions.** The most common adverse reactions are nausea, dry mouth, dizziness, constipation, fatigue, decreased appetite, anorexia, somnolence, and increased sweating. Nausea was the most common side effect that led to treatment discontinuation in clinical trials. The true incidence of sexual dysfunction is unknown; the long-term effects on body weight are also unknown. In clinical trials, treatment with duloxetine was associated with mean increases in BP averaging 2 mm Hg systolic and 0.5 mm Hg diastolic versus placebo. No studies have compared the BP effects of venlafaxine and duloxetine at equivalent therapeutic doses.

Close monitoring is suggested when using duloxetine in patients who have or are at risk for diabetes. Duloxetine has been shown to increase blood sugar and hemoglobin A1C levels during long-term treatment.

Patients with substantial alcohol use should not be treated with duloxetine because of possible hepatic effects. It also should not be prescribed for patients with hepatic insufficiency and end-stage renal disease or for patients with uncontrolled narrow-angle
Abrupt discontinuation of duloxetine should be avoided because it may produce a discontinuation syndrome similar to that of venlafaxine. A gradual dose reduction is recommended. Clinicians should avoid the use of duloxetine by pregnant and nursing women unless the potential benefits justify the potential risks.

**Drug Interactions**

Duloxetine is a moderate inhibitor of CYP450 enzymes.

**Laboratory Interferences**

Data are not currently available on laboratory interferences with duloxetine.

**Dosage and Administration**

Duloxetine is available in 20-, 30-, and 60-mg tablets. The recommended therapeutic, and maximum, dosage is 60 mg per day. The 20- and 30-mg doses are useful for either initial therapy or for twice-daily use as strategies to reduce side effects. In clinical trials, dosages of up to 120 mg per day were studied, but no consistent advantage in efficacy was noted at doses higher than 60 mg per day. Duloxetine thus does not appear to demonstrate a dosage–response curve. However, there were difficulties in tolerability with single doses above 60 mg. Accordingly, when dosages of 80 and 120 mg per day were used, they were administered as 40 or 60 mg twice daily. Because of limited clinical experience with duloxetine, it remains to be seen to what extent dosages above 60 mg per day will be necessary and whether this will actually require divided doses to make the drug tolerable.

**MILNACIPRAN AND LEVOMILNACIPRAN**

Milnacipran is only FDA approved for the treatment of fibromyalgia. Although some countries have approved milnacipran for general use as an antidepressant, efficacy is not as well established. Compared with venlafaxine, milnacipran is approximately five times more potent for inhibition of norepinephrine uptake than for 5-HT reuptake inhibition. Milnacipran has a half-life of approximately 8 hours and shows linear pharmacokinetics between doses of 50 and 250 mg per day. Metabolized in the liver, milnacipran has no active metabolites. Milnacipran is primarily excreted by the kidneys.

Milnacipran is available as 12.5-, 25-, 50-, and 100-mg tablets. The standard recommended milnacipran dose is as follows: day 1, 12.5 mg once daily; days 2 and 3, 12.5 mg twice daily; days 4 to 7, 25 mg twice daily; and day 7 and beyond, 50 mg twice daily.

Levomilnacipran was approved in 2013 by the FDA as a treatment for major depressive disorder (MOD) in adults. Levomilnacipran is an active enantiomer of the racemic drug milnacipran. In vitro studies have shown that it has greater potency for
norepinephrine reuptake inhibition than for serotonin reuptake inhibition and does not directly affect the uptake of dopamine or other neurotransmitters. It is taken once daily as a sustained-release formulation. In clinical trials, doses of 40 mg, 80 mg, or 120 mg improved symptoms compared with placebo.

The most common adverse reactions in the placebo-controlled trials were nausea, constipation, hyperhidrosis, increased heart rate, erectile dysfunction, tachycardia, vomiting, and palpitations. Rates of adverse events were generally consistent across the 40 to 120 mg dose range. The only dose-related adverse events were urinary hesitation and erectile dysfunction.

### 29.28 Selective Serotonin Reuptake Inhibitors

**Fluoxetine (Prozac)**, the first selective serotonin reuptake inhibitor (SSRI) marketed in the United States, rapidly captured the favor of both clinicians and the general public as reports emerged of dramatic patient responses to treatment of depression. Patients no longer experienced such side effects as dry mouth, constipation, sedation, orthostatic hypotension, and tachycardia, common side effects associated with the earlier antidepressant drugs—the tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs). It was also significantly safer when taken in overdose than any previously available antidepressant. A significant effect of fluoxetine’s popularity was that it helped ameliorate the long-standing stigma of depression and its treatment.

Fluoxetine was followed by other SSRIs. These include sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), and vilazodone (Viibryd). These drugs are all equally effective in treating depression but some are approved by the U.S. Food and Drug Administration (FDA) for multiple indications, such as major depression, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), premenstrual dysphoric disorder (PMDD), panic disorder, and social phobia (social anxiety disorder) (Table 29.28-1). Note that fluvoxamine is not FDA approved as an antidepressant, a fact that is due to a marketing decision. It is considered an antidepressant in other countries.

### Table 29.28-1

**Currently Approved Indications of the Selective Serotonin Reuptake Inhibitors in the United States for Adult and Pediatric Populations**
Although all SSRIs are equally effective, there are meaningful differences in pharmacodynamics, pharmacokinetics, and side effects, differences that might affect clinical responses among individual patients. This would explain why some patients have better clinical responses to a particular SSRI than another. The SSRIs have proven more problematic in terms of some side effects than the original clinical trials suggested. Quality-of-life–associated adverse effects such as nausea, sexual dysfunction, and weight gain sometimes mitigate the therapeutic benefits of the SSRIs. There can also be distressing withdrawal symptoms when SSRIs are stopped abruptly. This is especially true with paroxetine, but also occurs when other SSRIs with short half-lives are stopped.

### PHARMACOLOGICAL ACTIONS

#### Pharmacokinetics

A significant difference among the SSRIs is their broad range of serum half-lives. Fluoxetine has the longest half-life: 4 to 6 days; its active metabolite has a half-life of 7 to 9 days. The half-life of sertraline is 26 hours, and its less active metabolite has a half-life of 3 to 5 days. The half-lives of the other three, which do not have metabolites with significant pharmacological activity, are 35 hours for citalopram, 27 to 32 hours for escitalopram, 21 hours for paroxetine, and 15 hours for fluvoxamine. As a rule, the SSRIs are well absorbed after oral administration and have their peak effects in the range of 3 to 8 hours. Absorption of sertraline may be slightly enhanced by food.

There are also differences in plasma protein–binding percentages among the SSRIs, with sertraline, fluoxetine, and paroxetine being the most highly bound and escitalopram being the least bound.

All SSRIs are metabolized in the liver by the CYP450 enzymes. Because the SSRIs have such a wide therapeutic index, it is rare that other drugs produce problematic increases in SSRI concentrations. The most important drug–drug interactions involving the SSRIs occur as a result of the SSRIs inhibiting the metabolism of the coadministered medication. Each of the SSRIs possesses a potential for slowing or blocking the metabolism of many drugs (Table 29.28-2). Fluvoxamine is the most problematic of the
drugs in this respect. It has a marked effect on several of the CYP enzymes. Examples of clinically significant interactions include fluvoxamine and theophylline (Slo-Bid, Theo-Dur) through CYP1A2 interaction; fluvoxamine and clozapine (Clozaril) through CYP1A2 inhibition; and fluvoxamine with alprazolam (Xanax) or clonazepam (Klonopin) through CYP3A4 inhibition. Fluoxetine and paroxetine also possess significant effects on the CYP2D6 isozyme, which may interfere with the efficacy of opiate analogs, such as codeine and hydrocodone, by blocking the conversion of these agents to their active form. Thus, coadministration of fluoxetine and paroxetine with an opiate interferes with its analgesic effects. Sertraline, citalopram, and escitalopram are least likely to complicate treatment because of interactions.

CYP, cytochrome P450.

The pharmacokinetics of vilazodone (5 to 80 mg) are dose proportional. Steady-state plasma levels are achieved in about 3 days. Elimination of vilazodone is primarily by hepatic metabolism with a terminal half-life of approximately 25 hours.

**Pharmacodynamics**

The SSRIs are believed to exert their therapeutic effects through serotonin reuptake inhibition. They derive their name because they have little effect on reuptake of norepinephrine or dopamine. Often, adequate clinical activity and saturation of the 5-HT transporters are achieved at starting dosages. As a rule, higher dosages do not increase antidepressant efficacy but may increase the risk of adverse effects.

Citalopram and escitalopram are the most selective inhibitors of serotonin reuptake, with very little inhibition of norepinephrine or dopamine reuptake and very low affinities for histamine H₁, γ-aminobutyric acid (GABA), or benzodiazepine receptors. The other SSRIs have a similar profile except that fluoxetine weakly inhibits norepinephrine reuptake and binds to 5-HT₂C receptors, sertraline weakly inhibits norepinephrine and dopamine reuptake, and paroxetine has significant anticholinergic
activity at higher dosages and binds to nitric oxide synthase. The SSRI vilazodone has 5-HT1A receptor agonist properties. The clinical implications of the 5-HT1A receptor agonist effects are not yet evident.

A pharmacodynamic interaction appears to underlie the antidepressant effects of combined fluoxetine–olanzapine. When taken together, these drugs increase brain concentrations of norepinephrine. Concomitant use of SSRIs and drugs in the triptan class (sumatriptan [Imitrex], naratriptan [Amerge], rizatriptan [Maxalt], and zolmitriptan [Zomig]) may result in a serious pharmacodynamic interaction—the development of a serotonin syndrome (see “Precautions and Adverse Reactions”). However, many people use triptans while taking low doses of an SSRI for headache prophylaxis without adverse reaction. A similar reaction may occur when SSRIs are combined with tramadol (Ultram).

THERAPEUTIC INDICATIONS

Depression
In the United States, all SSRIs other than fluvoxamine have been approved by the FDA for treatment of depression. Several studies have found that antidepressants with serotonin-norepinephrine activity—drugs such as the MAOIs, TCAs, venlafaxine (Effexor), and mirtazapine (Remeron)—may produce higher rates of remission than SSRIs in head-to-head studies. The continued role of SSRIs as first-line treatment thus reflects their simplicity of use, safety, and broad spectrum of action.

Direct comparisons of individual SSRIs have not revealed any to be consistently superior to another. There nevertheless can be considerable diversity in response to the various SSRIs among individuals. For example, more than 50 percent of people who respond poorly to one SSRI will respond favorably to another. Thus, before shifting to non-SSRI antidepressants, it is most reasonable to try other agents in the SSRI class for persons who did not respond to the first SSRI.

Some clinicians have attempted to select a particular SSRI for a specific person on the basis of the drug’s unique adverse effect profile. For example, thinking that fluoxetine is an activating and stimulating SSRI, they may assume it is a better choice for an abulic person than paroxetine, which is presumed to be a sedating SSRI. These differences, however, usually vary from person to person. Analyses of clinical trial data show that the SSRIs are more effective in patients with more severe symptoms of major depression than those with milder symptoms.

Suicide. The FDA has issued a black box warning for antidepressants and suicidal thoughts and behavior in children and young adults. This warning is based on a decade-old analysis of clinical trial data. More recent, comprehensive reanalysis of data has shown that suicidal thoughts and behavior decreased over time for adult and geriatric patients treated with antidepressants as compared with placebo. No differences were found for youths. In adults, reduction in suicide ideation and attempts occurred through a reduction in depressive symptoms. In all age groups, severity of depression improved
with medication and was significantly related to suicide ideation or behavior. It appears that SSRIs, as well as serotonin-norepinephrine reuptake inhibitors (SNRIs), have a protective effect against suicide that is mediated by decreases in depressive symptoms with treatment. For youths, no significant effects of treatment on suicidal thoughts and behavior were found, although depression responded to treatment. No evidence of increased suicide risk was observed in youths receiving active medication. It is important to keep in mind that SSRIs, like all antidepressants, prevent potential suicides as a result of their primary action, the shortening and prevention of depressive episodes. In clinical practice, a few patients become especially anxious and agitated when started on an SSRI. The appearance of these symptoms could conceivably provoke or aggravate suicidal ideation. Thus, all depressed patients should be closely monitored during the period of maximum risk, the first few days and weeks they are taking SSRIs.

**Depression During Pregnancy and Postpartum.** Rates of relapse of major depression during pregnancy among women who discontinue, attempt to discontinue, or modify their antidepressant regimens are extremely high. Rates range from 68 to 100 percent of patients. Thus, many women need to continue taking their medication during pregnancy and postpartum. The impact of maternal depression on infant development is unknown. There is no increased risk for major congenital malformations after exposure to SSRIs during pregnancy. Thus, the risk of relapse into depression when a newly pregnant mother is taken off SSRIs is several-fold higher than the risk to the fetus of exposure to SSRIs.

There is some evidence suggesting increased rates of special care nursery admissions after delivery for children of mothers taking SSRIs. There is also a potential for a discontinuation syndrome with paroxetine. However, there is an absence of clinically significant neonatal complications associated with SSRI use.

Studies that have followed children into their early school years have failed to find any perinatal complications, congenital fetal anomalies, decreases in global intelligence quotient (IQ), language delays, or specific behavioral problems attributable to the use of fluoxetine during pregnancy.

Postpartum depression (with or without psychotic features) affects a small percentage of mothers. Some clinicians start administering SSRIs if the postpartum blues extend beyond a few weeks or if a woman becomes depressed during pregnancy. The head start afforded by starting SSRI administration during pregnancy if a woman is at risk for postpartum depression also protects the newborn, toward whom the woman may have harmful thoughts after parturition.

Babies whose mothers are taking an SSRI in the later part of pregnancy may be at a slight risk of developing pulmonary hypertension. Data about the risk of this side effect are inconclusive, but it is estimated to involve 1 to 2 babies for 1,000 births. Paroxetine should be avoided during pregnancy.

The FDA has classified paroxetine as a *pregnancy Category D* medication. In 2005, the FDA issued an alert that paroxetine increases the risk of birth defects, particularly heart defects, when women take it during the first 3 months of pregnancy. Paroxetine should
usually not be taken during pregnancy, but for some women who have already been
taking paroxetine, the benefits of continuing paroxetine may be greater than the
potential risk to the baby. Women taking paroxetine who are pregnant, think they may
be pregnant, or plan to become pregnant should talk to their physicians about the
potential risks of taking paroxetine during pregnancy.

The FDA alert was based on the findings of studies that showed that women who took
paroxetine during the first 3 months of pregnancy were about one and a half to two
times as likely to have a baby with a heart defect as women who received other
antidepressants or women in the general population. Most of the heart defects in these
studies were not life-threatening and happened mainly in the inside walls of the heart
muscle where repairs can be made if needed (atrial and ventricular septal defects).
Sometimes these septal defects resolve without treatment. In one of the studies, the risk
of heart defects in babies whose mothers had taken paroxetine early in pregnancy was 2
percent, compared with a 1 percent risk in the whole population. In the other study, the
risk of heart defects in babies whose mothers had taken paroxetine in the first 3 months
of pregnancy was 1.5 percent, compared with 1 percent in babies whose mothers had
taken other antidepressants in the first 3 months of pregnancy. This study also showed
that women who took paroxetine in the first 3 months of pregnancy were about twice as
likely to have a baby with any birth defect as women who took other antidepressants.

Very small amounts of SSRIs are found in breast milk and no harmful effects have
been found in breastfed babies. Concentrations of sertraline and escitalopram are
especially low in breast milk. However, in some cases, reported concentrations may be
higher than average. No decision regarding the use of an SSRI is risk free. It is thus
important to document that communication of potential risks to the patient has taken
place.

Depression in Elderly and Medically Ill Persons. The SSRIs are safe and
well tolerated when used to treat elderly and medically ill persons. As a class, they have
little or no cardiotoxic, anticholinergic, antihistaminergic, or α-adrenergic adverse
effects. Paroxetine does have some anticholinergic activity, which may lead to
constipation and worsening of cognition. The SSRIs can produce subtle cognitive
deficits, prolonged bleeding time, and hyponatremia, all of which may impact the health
of this population. The SSRIs are effective in poststroke depression and dramatically
reduce the symptom of crying.

Depression in Children. The use of SSRI antidepressants in children and
adolescents has been controversial. Few studies have shown clear-cut benefits from the
use of these drugs, and studies show that there may be an increase in suicidal or
aggressive impulses. However, some children and adolescents do exhibit dramatic
responses to these drugs in terms of depression and anxiety. Fluoxetine has most
consistently demonstrated effectiveness in reducing symptoms of depressive disorder in
both children and adolescents. This may be a function of the quality of the clinical trials
involved. Sertraline has been shown to be effective in treating social anxiety disorder in
this population, especially when combined with cognitive-behavioral therapy. Given the potential negative effect of untreated depression and anxiety in a young population and the uncertainty about many aspects of how children and adolescents might react to medication, any use of SSRIs should be undertaken only within the context of comprehensive management of the patient.

Anxiety Disorders

**Obsessive-Compulsive Disorder.** Fluvoxamine, paroxetine, sertraline, and fluoxetine are indicated for treatment of OCD in persons older than the age of 18 years. Fluvoxamine and sertraline have also been approved for treatment of children with OCD (ages 6 to 17 years). About 50 percent of persons with OCD begin to show symptoms in childhood or adolescence, and more than half of these respond favorably to medication. Beneficial responses can be dramatic. Long-term data support the model of OCD as a genetically determined, lifelong condition that is best treated continuously with drugs and cognitive-behavioral therapy from the onset of symptoms in childhood throughout the lifespan.

SSRI dosages for OCD may need to be higher than those required to treat depression. Although some response can be seen in the first few weeks of treatment, it may take several months for the maximum effects to become evident. Patients who fail to obtain adequate relief of their OCD symptoms with an SSRI often benefit from the addition of a small dose of risperidone (Risperdal). Apart from the extrapyramidal side effects of risperidone, patients should be monitored for increases in prolactin levels when this combination is used. Clinically, hyperprolactinemia may manifest as gynecomastia and galactorrhea (in both men and women) and loss of menses.

A number of disorders are now considered to be within the OCD spectrum. This includes a number of conditions and symptoms characterized by nonsuicidal self-mutilation, such as trichotillomania, eyebrow picking, nose picking, nail biting, compulsive picking of skin blemishes, and cutting. Patients with these behaviors benefit from treatment with SSRIs. Other spectrum disorders include compulsive gambling, compulsive shopping, hypochondriasis, and body dysmorphic disorder.

**Panic Disorder.** Paroxetine and sertraline are indicated for treatment of panic disorder, with or without agoraphobia. These agents work less rapidly than do the benzodiazepines alprazolam and clonazepam but are far superior to the benzodiazepines for treatment of panic disorder with comorbid depression. Citalopram, fluvoxamine, and fluoxetine also may reduce spontaneous or induced panic attacks. Because fluoxetine can initially heighten anxiety symptoms, persons with panic disorder must begin taking small dosages (5 mg a day) and increase the dosage slowly. Low doses of benzodiazepines may be given to manage this side effect.

**Social Anxiety Disorder.** SSRIs are effective agents in the treatment of social phobia. They reduce both symptoms and disability. The response rate is comparable to
that seen with the MAOI phenelzine (Nardil), the previous standard treatment. The SSRIs are safer to use than MAOIs or benzodiazepines.

**Posttraumatic Stress Disorder.** Pharmacotherapy for PTSD must target specific symptoms in three clusters: re-experiencing, avoidance, and hyperarousal. For long-term treatment, SSRIs appear to have a broader spectrum of therapeutic effects on specific PTSD symptom clusters than do TCAs and MAOIs. Benzodiazepine augmentation is useful in the acute symptomatic state. The SSRIs are associated with marked improvement of both intrusive and avoidant symptoms.

**Generalized Anxiety Disorder.** The SSRIs may be useful for the treatment of specific phobias, generalized anxiety disorder, and separation anxiety disorder. A thorough, individualized evaluation is the first approach, with particular attention to identifying conditions amenable to drug therapy. In addition, cognitive-behavioral or other psychotherapies can be added for greater efficacy.

**Bulimia Nervosa and Other Eating Disorders**

Fluoxetine is indicated for treatment of bulimia, which is best done in the context of psychotherapy. Dosages of 60 mg a day are significantly more effective than 20 mg a day. In several well-controlled studies, fluoxetine in dosages of 60 mg a day was superior to placebo in reducing binge eating and induced vomiting. Some experts recommend an initial course of cognitive-behavioral therapy alone. If there is no response in 3 to 6 weeks, then fluoxetine administration is added. The appropriate duration of treatment with fluoxetine and psychotherapy has not been determined.

Fluvoxamine was not effective at a statistically significant level in one double-blind, placebo-controlled trial for inpatients with bulimia.

**Anorexia Nervosa.** Fluoxetine has been used in inpatient treatment of anorexia nervosa to attempt to control comorbid mood disturbances and obsessive-compulsive symptoms. However, at least two careful studies, one of 7 months’ and one of 24 months’ duration, failed to find that fluoxetine affected the overall outcome and the maintenance of weight. Effective treatments for anorexia include cognitive-behavioral, interpersonal, psychodynamic, and family therapies in addition to a trial with SSRIs.

**Obesity.** Fluoxetine, in combination with a behavioral program, has been shown to be only modestly beneficial for weight loss. A significant percentage of all persons who take SSRIs, including fluoxetine, lose weight initially but later may gain weight. However, all SSRIs may cause initial weight gain.

**Premenstrual Dysphoric Disorder.** PMDD is characterized by debilitating mood and behavioral changes in the week preceding menstruation that interfere with normal functioning. Sertraline, paroxetine, fluoxetine, and fluvoxamine have been reported to
reduce the symptoms of PMDD. Controlled trials of fluoxetine and sertraline administered either throughout the cycle or only during the luteal phase (the 2-week period between ovulation and menstruation) showed both schedules to be equally effective.

An additional observation of unclear significance was that fluoxetine was associated with changing the duration of the menstrual period by more than 4 days, either lengthening or shortening it. The effects of SSRIs on menstrual cycle length are mostly unknown and may warrant careful monitoring in women of reproductive age.
Off-Label Uses

Premature Ejaculation. The antiorgasmic effects of SSRIs make them useful as a treatment for men with premature ejaculation. The SSRIs permit intercourse for a significantly longer period and are reported to improve sexual satisfaction in couples in which the man has premature ejaculation. Fluoxetine and sertraline have been shown to be effective for this purpose.

Paraphilias. The SSRIs may reduce obsessive-compulsive behavior in people with paraphilias. The SSRIs diminish the average time per day spent in unconventional sexual fantasies, urges, and activities. Evidence suggests a greater response for sexual obsessions than for paraphilic behavior.

Autism. Obsessive-compulsive behavior, poor social relatedness, and aggression are prominent autistic features that may respond to serotonergic agents such as SSRIs and clomipramine (Anafranil). Sertraline and fluvoxamine have been shown in controlled and open-label trials to mitigate aggressiveness, self-injurious behavior, repetitive behaviors, some degree of language delay, and (rarely) lack of social relatedness in adults with autistic spectrum disorders. Fluoxetine has been reported to be effective for features of autism in children, adolescents, and adults.

Precautions and Adverse Reactions

SSRI side effects need to be considered in terms of their onset, duration, and severity. For example, nausea and jitteriness are early, generally mild, and time-limited side effects. Although SSRIs share common side effect profiles, individual drugs in this class may cause a higher rate or carry a more severe risk of certain side effects depending on the patient.

Sexual Dysfunction

All SSRIs cause sexual dysfunction, and it is the most common adverse effect of SSRIs associated with long-term treatment. It has an estimated incidence of between 50 and 80 percent. The most common complaints are anorgasmia, inhibited orgasm, and decreased libido. Some studies suggest that sexual dysfunction is dose related, but this has not been clearly established. Unlike most of the other adverse effects of SSRIs, sexual inhibition rarely resolves in the first few weeks of use but usually continues as long as the drug is taken. In some cases, there may be improvement over time.

Strategies to counteract SSRI-induced sexual dysfunction are numerous, and none has been proven to be very effective. Some reports suggest decreasing the dosage or adding bupropion (Wellbutrin) or amphetamine. Reports have described successful treatment of SSRI-induced sexual dysfunction with agents such as sildenafil (Viagra), which are used to treat erectile dysfunction. Ultimately, patients may need to be switched to
antidepressants that do not interfere with sexual functioning, drugs such as mirtazapine or bupropion.

**Gastrointestinal Adverse Effects**

Gastrointestinal (GI) side effects are very common and are mediated largely through effects on the serotonin 5-HT\textsubscript{3} receptor. The most frequent GI complaints are nausea, diarrhea, anorexia, vomiting, flatulence, and dyspepsia. Sertraline and fluvoxamine produce the most intense GI symptoms. Delayed-release paroxetine, compared with the immediate-release preparation of paroxetine, has less intense GI side effects during the first week of treatment. However, paroxetine, because of its anticholinergic activity, frequently causes constipation. Nausea and loose stools are usually dose related and transient, usually resolving within a few weeks. Sometimes flatulence and diarrhea persist, especially during sertraline treatment. Initial anorexia may also occur and is most common with fluoxetine. SSRI-induced appetite and weight loss begin as soon as the drug is taken and peak at 20 weeks, after which weight often returns to baseline. Up to one third of persons taking SSRIs will gain weight, sometimes more than 20 lbs. This effect is mediated through a metabolic mechanism, increase in appetite, or both. It happens gradually and is usually resistant to diet and exercise regimens. Paroxetine is associated with more frequent, rapid, and pronounced weight gain than the other SSRIs, especially among young women.

**Cardiovascular Effects**

All SSRIs can lengthen the QT interval in otherwise healthy people and cause drug-induced long QT syndrome, especially when taken in overdose. The risk of QTc prolongation increases when an antidepressant and an antipsychotic are used in combination, an increasingly common practice. Citalopram stands out as the SSRI with the most pronounced effect QT intervals. A QT study to assess the effects of 20-mg and 60-mg doses of citalopram on the QT interval in adults, compared with placebo, found a maximum mean prolongation in the individually corrected QT intervals were 8.5 milliseconds for 20 mg citalopram and 18.5 milliseconds for 60 mg. For 40 mg, prolongation of the corrected QT interval was estimated to be 12.6 milliseconds. Based on these findings, the FDA has issued the following recommendation regarding citalopram use:

- 20 mg a day is the maximum recommended dose for patients with hepatic impairment, who are older than 60 years of age, who are CYP2C19 poor metabolizers, or who are taking concomitant cimetidine (Tagamet).
- No longer prescribe at doses greater than 40 mg a day.
- Do not use in patients with congenital long QT syndrome.
- Correct hypokalemia and hypomagnesemia before administering citalopram.
- Monitor electrolytes as clinically indicated.
Consider more frequent electrocardiograms in patients with congestive heart failure, bradyarrhythmias, or patients on concomitant medications that prolong the QT interval.

The fact that citalopram carries greater risk of causing fatal rhythm abnormalities was confirmed in a review of 469 SSRI poisoning admissions. Accordingly, patients should be advised to contact their prescriber immediately if they experience signs and symptoms of an abnormal heart rate or rhythm while taking citalopram.

The effect of vilazodone (20, 40, 60, and 80 mg) on the QTc interval was evaluated and a small effect was observed. The upper bound of the 90 percent confidence interval for the largest placebo-adjusted, baseline-corrected QTc interval was below 10 milliseconds, based on the individual correction method (QTcI). This is below the threshold for clinical concern. However, it is unknown whether 80 mg is adequate to represent a high clinical exposure condition.

Physicians should consider whether the benefits of androgen deprivation therapy outweigh the potential risks in SSRI treated patients with prostate cancer as reductions in androgen levels can cause QTc interval prolongation.

Dextromethorphan/Quinidine (Nuedexta) is available as a treatment for pseudobulbar affect, which is defined by involuntary, sudden, and frequent episodes of laughing or crying that are generally out of proportion or inappropriate to the situation. Quinidine that can prolong the QT interval is a potent inhibitor of CYP2D6. It should not be used with other medications that prolong the QT interval and are metabolized by CYP2D6. This drug should be used with caution with any medications that can prolong the QT interval and inhibit CYP3A4, particularly in patients with cardiac disease.

Antepartum use of SSRIs is sometimes associated with QTc interval prolongation in exposed neonates. In a review of 52 newborns exposed to SSRIs in the immediate antepartum period and 52 matched control subjects, the mean QTc was significantly longer in the group of newborns exposed to antidepressants as compared with control subjects. Five (10 percent) newborns exposed to SSRIs had a markedly prolonged QTc interval (greater than 460 milliseconds) compared with none of the unexposed newborns. The longest QTc interval observed among exposed newborns was 543 milliseconds. All of the drug-associated repolarization abnormalities normalized in subsequent electrocardiographic tracings.

**Headaches**

The incidence of headache in SSRI trials was 18 to 20 percent, only 1 percentage point higher than the placebo rate. Fluoxetine is the most likely to cause headache. On the other hand, all SSRIs are effective prophylaxis against both migraine and tension-type headaches in many persons.

**Central Nervous System Adverse Effects**

**Anxiety.** Fluoxetine may cause anxiety, particularly in the first few weeks of
treatment. However, these initial effects usually give way to an overall reduction in anxiety after a few weeks. Increased anxiety is caused considerably less frequently by paroxetine and escitalopram, which may be better choices if sedation is desired, as in mixed anxiety and depressive disorders.

**Insomnia and Sedation.** The major effect SSRIs exert in the area of insomnia and sedation is improved sleep resulting from treatment of depression and anxiety. However, as many as 25 percent of persons taking SSRIs note trouble sleeping, excessive somnolence, or overwhelming fatigue. Fluoxetine is the most likely to cause insomnia, for which reason it is often taken in the morning. Sertraline and fluvoxamine are about equally likely to cause insomnia as somnolence, and citalopram and especially paroxetine often cause somnolence. Escitalopram is more likely to interfere with sleep than its isomer, citalopram. Some persons benefit from taking their SSRI dose before going to bed, but others prefer to take it the morning. SSRI-induced insomnia can be treated with benzodiazepines, trazodone (Desyrel) (clinicians must explain the risk of priapism), or other sedating medicines. Significant SSRI-induced somnolence often requires switching to use of another SSRI or bupropion.

**Other Sleep Effects.** Many persons taking SSRIs report recalling extremely vivid dreams or nightmares. They describe sleep as “busy.” Other sleep effects of the SSRIs include bruxism, restless legs, nocturnal myoclonus, and sweating.

**Emotional Blunting.** Emotional blunting is a largely overlooked but frequent side effect associated with chronic SSRI use. Patients report an inability to cry in response to emotional situations, a feeling of apathy or indifference, or a restriction in the intensity of emotional experiences. This side effect often leads to treatment discontinuation, even when the drugs provide relief from depression or anxiety.

**Yawning.** Close clinical observation of patients taking SSRIs reveals an increase in yawning. This side effect is not a reflection of fatigue or poor nocturnal sleep but is the result of SSRI effects on the hypothalamus.

**Seizures.** Seizures have been reported in 0.1 to 0.2 percent of all patients treated with SSRIs, an incidence comparable to that reported with other antidepressants and not significantly different from that with placebo. Seizures are more frequent at the highest doses of SSRIs (e.g., fluoxetine 100 mg a day or higher).

**Extrapyramidal Symptoms.** The SSRIs may rarely cause akathisia, dystonia, tremor, cogwheel rigidity, torticollis, opisthotonos, gait disorders, and bradykinesia. Rare cases of tardive dyskinesia have been reported. Some people with well-controlled Parkinson’s disease may experience acute worsening of their motor symptoms when they take SSRIs.
Anticholinergic Effects
Paroxetine has mild anticholinergic activity that causes dry mouth, constipation, and sedation in a dose-dependent fashion. Nevertheless, most persons taking paroxetine do not experience cholinergic adverse effects. Other SSRIs are associated with dry mouth, but this effect is not mediated by muscarinic activity.

Hematologic Adverse Effects
The SSRIs can cause functional impairment of platelet aggregation but not a reduction in platelet number. Easy bruising and excessive or prolonged bleeding manifest this pharmacological effect. When patients exhibit these signs, a test for bleeding time should be performed. Special monitoring is suggested when patients use SSRIs in conjunction with anticoagulants or aspirin. Concurrent use of SSRIs and nonsteroidal anti-inflammatory drugs (NSAIDs) is associated with a significantly increased risk of gastric bleeding. In cases where this combination is necessary, use of proton pump inhibitors should be considered.

Electrolyte and Glucose Disturbances
The SSRIs may acutely decrease glucose concentrations; therefore, diabetic patients should be carefully monitored. Long-term use may be associated with increased glucose levels, although it remains to be proven whether this is the result of a pharmacological effect. It is possible that antidepressant users have other characteristics that raise their odds of developing diabetes or are more likely to be diagnosed with diabetes or other medical conditions as a result of being in treatment for depression.

Cases of SSRI-associated hyponatremia and the syndrome of inappropriate antidiuretic hormone have been seen in some patients, especially those who are older or treated with diuretics.

Endocrine and Allergic Reactions
The SSRIs can increase prolactin levels and cause mammoplasia and galactorrhea in both men and women. Breast changes are reversible upon discontinuation of the drug, but this may take several months to occur.

Various types of rashes appear in about 4 percent of all patients; in a small subset of these patients, the allergic reaction may generalize and involve the pulmonary system, resulting rarely in fibrotic damage and dyspnea. SSRI treatment may have to be discontinued in patients with drug-related rashes.

Serotonin Syndrome
Concurrent administration of an SSRI with an MAOI, l-tryptophan, or lithium (Eskalith) can raise plasma serotonin concentrations to toxic levels, producing a constellation of symptoms called serotonin syndrome. This serious and possibly fatal syndrome of
serotonin overstimulation comprises, in order of appearance as the condition worsens, 
(1) diarrhea; (2) restlessness; (3) extreme agitation, hyperreflexia, and autonomic 
instability with possible rapid fluctuations in vital signs; (4) myoclonus, seizures, 
hyperthermia, uncontrollable shivering, and rigidity; and (5) delirium, coma, status 
epilepticus, cardiovascular collapse, and death.

Treatment of serotonin syndrome consists of removing the offending agents and 
promptly instituting comprehensive supportive care with nitroglycerine, cyproheptadine 
(Periactin), methysergide (Sansert), cooling blankets, chlorpromazine (Thorazine), 
dantrolene (Dantrium), benzodiazepines, anticonvulsants, mechanical ventilation, and 
paralyzing agents.

**Sweating**

Some patients experience sweating while being treated with SSRIs. The sweating is 
unrelated to ambient temperature. Nocturnal sweating may drench bed sheets and 
require a change of night clothes. Terazosin (Hytrin), 1 or 2 mg per day, is often 
dramatically effective in counteracting sweating.

**Overdose**

The adverse reactions associated with overdose of vilazodone at doses of 200 to 280 mg 
as observed in clinical trials included serotonin syndrome, lethargy, restlessness, 
hallucinations, and disorientation.

**Selective Serotonin Reuptake Inhibitor Withdrawal**

The abrupt discontinuance of SSRI use, especially one with a shorter half-life such as 
paroxetine or fluvoxamine, has been associated with a withdrawal syndrome that may 
include dizziness, weakness, nausea, headache, rebound depression, anxiety, insomnia, 
poor concentration, upper respiratory symptoms, paresthesias, and migraine-like 
symptoms. It usually does not appear until after at least 6 weeks of treatment and 
usually resolves spontaneously in 3 weeks. Persons who experienced transient adverse 
effects in the first weeks of taking an SSRI are more likely to experience discontinuation 
symptoms.

Fluoxetine is the SSRI least likely to be associated with this syndrome because the half-
life of its metabolite is more than 1 week, and it effectively tapers itself. Fluoxetine has 
therefore been used in some cases to treat the discontinuation syndrome caused by 
termination of other SSRIs. Nevertheless, a delayed and attenuated withdrawal 
syndrome occurs with fluoxetine as well.

**DRUG INTERACTIONS**

The SSRIs do not interfere with most other drugs. A serotonin syndrome (Table 29.28-3) 
can develop with concurrent administration of MAOIs, l-tryptophan, lithium, or other
antidepressants that inhibit reuptake of serotonin. Fluoxetine, sertraline, and paroxetine can raise plasma concentrations of TCAs, which can cause clinical toxicity. A number of potential pharmacokinetic interactions have been described based on in vitro analyses of the CYP enzymes, but clinically relevant interactions are rare. SSRIs that inhibit CYP2D6 may interfere with the analgesic effects of hydrocodone and oxycodone. These drugs can also reduce the effectiveness of tamoxifen (Nolvadex, Soltamox). Combined use of SSRIs and NSAIDs increases the risk of gastric bleeding.

The SSRIs, particularly fluvoxamine, should not be used with clozapine because it raises clozapine concentrations, increasing the risk of seizure. The SSRIs may increase the duration and severity of zolpidem (Ambien)-induced side effects, including hallucinations.

**Fluoxetine**

Fluoxetine can be administered with tricyclic drugs, but the clinician should use low dosages of the tricyclic drug. Because it is metabolized by the hepatic enzyme CYP2D6, fluoxetine may interfere with the metabolism of other drugs in the 7 percent of the population who have an inefficient isoform of this enzyme, the so-called poor metabolizers. Fluoxetine may slow down the metabolism of carbamazepine (Tegretol), antineoplastic agents, diazepam (Valium), and phenytoin (Dilantin). Drug interactions have been described for fluoxetine that may affect the plasma levels of benzodiazepines, antipsychotics, and lithium. Fluoxetine and other SSRIs may interact with warfarin (Coumadin), increasing the risk of bleeding and bruising.

**Sertraline**

Sertraline may displace warfarin from plasma proteins and may increase the prothrombin time. The drug interaction data on sertraline support a generally similar profile to that of fluoxetine, although sertraline does not interact as strongly with the CYP2D6 enzyme.

**Paroxetine**

Paroxetine has a higher risk for drug interactions than does either fluoxetine or sertraline because it is a more potent inhibitor of the CYP2D6 enzyme. Cimetidine can increase the concentration of sertraline and paroxetine, and phenobarbital (Luminal) and phenytoin can decrease the concentration of paroxetine. Because of the potential
for interference with the CYP2D6 enzyme, the coadministration of paroxetine with other antidepressants, phenothiazines, and antiarrhythmic drugs should be undertaken with caution. Paroxetine may increase the anticoagulant effect of warfarin. Coadministration of paroxetine and tramadol may precipitate serotonin syndrome in elderly persons.

**Fluvoxamine**

Among the SSRIs, fluvoxamine appears to present the most risk for drug–drug interactions. Fluvoxamine is metabolized by the enzyme CYP3A4, which may be inhibited by ketoconazole (Nizoral). Fluvoxamine may increase the half-life of alprazolam, triazolam (Halcion), and diazepam, and it should not be coadministered with these agents. Fluvoxamine may increase theophylline levels threefold and warfarin levels twofold, with important clinical consequences; thus, the serum levels of the latter drugs should be closely monitored and the doses adjusted accordingly. Fluvoxamine raises concentrations and may increase the activity of clozapine, carbamazepine, methadone (Dolophine, Methadose), propranolol (Inderal), and diltiazem (Cardizem). Fluvoxamine has no significant interactions with lorazepam (Ativan) or digoxin (Lanoxin).

**Citalopram**

Citalopram is not a potent inhibitor of any CYP enzymes. Concurrent administration of cimetidine increases concentrations of citalopram by about 40 percent. Citalopram does not significantly affect the metabolism of, nor is its metabolism significantly affected by, digoxin, lithium, warfarin, carbamazepine, or imipramine (Tofranil). Citalopram increases the plasma concentrations of metoprolol (Lopressor) twofold, but this usually has no effect on blood pressure or heart rate. Data on coadministration of citalopram and potent inhibitors of CYP3A4 or CYP2D6 are not available.

**Escitalopram**

Escitalopram is a moderate inhibitor of CYP2D6 and has been shown to significantly raise desipramine (Norpramin) and metoprolol concentrations.

**Vilazodone**

Vilazodone dose should be reduced to 20 mg when co-administered with CYP3A4 strong inhibitors. Concomitant use with inducers of CYP3A4 can result in inadequate drug concentrations and may diminish effectiveness. The effect of CYP3A4 inducers on systemic exposure of vilazodone has not been evaluated.

**LABORATORY INTERFERENCES**

The SSRIs do not interfere with any laboratory tests.
Fluoxetine

Fluoxetine is available in 10- and 20-mg capsules, in a scored 10-mg tablet, as a 90-mg enteric-coated capsule for once-weekly administration, and as an oral concentrate (20 mg/5 mL). Fluoxetine is also marketed as Sarafem for PMDD. For depression, the initial dosage is usually 10 or 20 mg orally each day, usually given in the morning, because insomnia is a potential adverse effect of the drug. Fluoxetine should be taken with food to minimize the possible nausea. The long half-lives of the drug and its metabolite contribute to a 4-week period to reach steady-state concentrations. Twenty milligrams is often as effective as higher doses for treating depression. The maximum dosage recommended by the manufacturer is 80 mg a day. To minimize the early side effects of anxiety and restlessness, some clinicians initiate fluoxetine use at 5 to 10 mg a day either with the scored 10-mg tablet or by using the liquid preparation. Alternatively, because of the long half-life of fluoxetine, its use can be initiated with an every-other-day administration schedule. The dosage of fluoxetine (and other SSRIs) that is effective in other indications may differ from the dosage generally used for depression.

Sertraline

Sertraline is available in scored 25-, 50-, and 100-mg tablets. For the initial treatment of depression, sertraline use should be initiated with a dosage of 50 mg once daily. To limit the GI effects, some clinicians begin at 25 mg a day and increase to 50 mg a day after 3 weeks. Patients who do not respond after 1 to 3 weeks may benefit from dosage increases of 50 mg every week up to a maximum of 200 mg given once daily. Sertraline can be administered in the morning or the evening. Administration after eating may reduce the GI adverse effects. Sertraline oral concentrate (1 mL = 20 mg) has 12 percent alcohol content and must be diluted before use. When used to treat panic disorder, sertraline should be initiated at 25 mg to reduce the risk of provoking a panic attack.

Paroxetine

Immediate-release paroxetine is available in scored 20-mg tablets; in unscored 10-, 30-, and 40-mg tablets; and as an orange-flavored 10-mg/5-mL oral suspension. Paroxetine use for the treatment of depression is usually initiated at a dosage of 10 or 20 mg a day. An increase in the dosage should be considered when an adequate response is not seen in 1 to 3 weeks. At that point, the clinician can initiate upward dose titration in 10-mg increments at weekly intervals to a maximum of 50 mg a day. Persons who experience GI upset may benefit by taking the drug with food. Paroxetine can be taken initially as a single daily dose in the evening; higher dosages may be divided into two doses per day.

A delayed-release formulation of paroxetine, paroxetine CR, is available in 12.5-, 25-,
and 37.5-mg tablets. The starting dosages of paroxetine CR are 25 mg per day for depression and 12.5 mg per day for panic disorder.

Paroxetine is the SSRI most likely to produce a discontinuation syndrome because plasma concentrations decrease rapidly in the absence of continuous dosing. To limit the development of symptoms of abrupt discontinuation, paroxetine use should be tapered gradually, with dosage reductions every 2 to 3 weeks.

**Fluvoxamine**

Fluvoxamine is the only SSRI not approved by the FDA as an antidepressant. It is indicated for social anxiety disorder and OCD. It is available in unscored 25-mg tablets and scored 50- and 100-mg tablets. The effective daily dosage range is 50 to 300 mg a day. A usual starting dosage is 50 mg once a day at bedtime for the first week, after which the dosage can be adjusted according to the adverse effects and clinical response. Dosages above 100 mg a day may be divided into twice-daily dosing. A temporary dosage reduction or slower upward titration may be necessary if nausea develops over the first 2 weeks of therapy. Although fluvoxamine can also be administered as a single evening dose to minimize its adverse effects, its short half-life may lead to interdose withdrawal. An extended-release formulation is available in 100- and 150-mg dose strengths. All fluvoxamine formulations should be swallowed with food without chewing the tablet. Abrupt discontinuation of fluvoxamine may cause a discontinuation syndrome owing to its short half-life.

**Citalopram**

Citalopram is available in 20- and 40-mg scored tablets and as a liquid (10 mg/5 mL). The usual starting dosage is 20 mg a day for the first week, after which it usually is increased to 40 mg a day. For elderly persons or persons with hepatic impairment, 20 mg a day is recommended, with an increase to 40 mg a day only if there is no response at 20 mg a day. Tablets should be taken once daily in either the morning or the evening with or without food.

**Escitalopram**

Escitalopram is available as 10- and 20-mg scored tablets, as well as an oral solution at a concentration of 5 mg/5 mL. The recommended dosage of escitalopram is 10 mg per day. In clinical trials, no additional benefit was noted when 20 mg per day was used.

**Vilazodone**

Vilazodone is available as 10-, 20-, and 40-mg tablets. The recommended therapeutic dose of vilazodone is 40 mg once daily. Treatment should be titrated, starting with an initial dose of 10 mg once daily for 7 days, followed by 20 mg once daily for an additional 7 days, and then an increase to 40 mg once daily. Vilazodone should be taken with food. If vilazodone is taken without food, inadequate drug concentrations may
result and the drug’s effectiveness may be diminished. Vilazodone is not approved for use in children. The safety and efficacy of vilazodone in pediatric patients have not been studied. No dose adjustment is recommended on the basis of age. No dose adjustment is recommended in patients with mild or moderate hepatic impairment. Vilazodone has not been studied in patients with severe hepatic impairment. No dose adjustment is recommended in patients with mild, moderate, or severe renal impairment.

Pregnancy and Breast-Feeding
With the exception of paroxetine, the SSRIs are safe to take during pregnancy when deemed necessary for treatment of the mother. There are no controlled human data regarding vilazodone use during pregnancy nor are there human data regarding drug concentrations in breast milk. Transient QTc prolongation has been noted in newborns whose mother was being treated with an SSRI during pregnancy.

Loss of Efficacy
Some patients report a diminished response or total loss of response to SSRIs with recurrence of depressive symptoms while remaining on a full dose of medication. The exact mechanism of this so-called poop-out is unknown, but the phenomenon is very real. Potential remedies for the attenuation of response to SSRIs include increasing or decreasing the dosage, tapering drug use, and then rechallenging with the same medication, switching to another SSRI or non-SSRI antidepressant, and augmenting with bupropion or another augmentation agent.

Vortioxetine (Brintellix)
Vortioxetine works mainly as an inhibitor of serotonin (5-HT) reuptake, but it has a more complex pharmacologic profile than other SSRIS. It also acts as an agonist at 5-HT1A receptors, a partial agonist at 5-HT1B receptors and an antagonist at 5-HT3, 5-HT1D and 5-HT7 receptors. The contribution of each of these activities to the drug’s antidepressant effect has not been established, but it is the only compound with this combination of pharmacodynamic actions.

Side effects seen during the trials include, but are not limited to, nausea, constipation and vomiting.

The recommended starting dose is 10 mg administered orally once daily without regard to meals. The dose should then be increased to 20 mg/day, as tolerated. A dose of 5 mg/day should be considered for patients who do not tolerate higher doses.

The maximum recommended dose of Vortioxetine is 10 mg/day in known CYP2D6 poor metabolizers. Reduction of the dose of Vortioxetine by one half is suggested when patients are receiving a CYP2D6 strong inhibitor (e.g., bupropion, fluoxetine, paroxetine, or quinidine) concomitantly. The dose should be increased to the original dose of vortioxetine in patients who stop taking CYP inducers, (e.g., rifampin,
carbamazepine, or phenytoin) increasing its dose should be considered. This is especially important when a strong CYP inducer is coadministered for greater than 14 days. The maximum recommended dose should not exceed three times the original dose. The dose of vortioxetine should be reduced to the original level within 14 days, when the inducer is discontinued.

Although vortioxetine can be abruptly discontinued, in placebo-controlled trials patients experienced transient adverse reactions such as headache and muscle tension following abrupt discontinuation of vortioxetine 15 mg/day or 20 mg/day. To avoid these adverse reactions, it is recommended that the dose be decreased to 10 mg/day for one week before full discontinuation of vortioxetine 15 mg/day or 20 mg/day.

Vortioxetine is available in 5 milligram (mg), 10 mg, 15 mg and 20 mg tablets.

29.29 Serotonin–Dopamine Antagonists and Similarly Acting Drugs (Second-Generation or Atypical Antipsychotics)

The serotonin–dopamine antagonists (SDAs), also known as second-generation or atypical antipsychotic drugs, are a group of pharmacologically diverse drugs that have largely supplanted the older dopamine receptor antagonists (DRAs). The term atypical is used because these drugs differ in their side effect profiles, most notably a lower risk of extrapyramidal side effects (EPS), and have spectra of action that are broader than those of the DRAs. In contrast to the earlier antipsychotic drugs, the SDAs have significant effects on both the dopamine and serotonin systems. Their pharmacology is complex, with individual drugs in this group having multiple neurotransmitter effects. All SDAs are indicated for the treatment of schizophrenia. Most of these second-generation antipsychotic drugs have also received approval as monotherapy or adjunctive therapy in the treatment of bipolar disorder. Some have also been approved as adjuncts for treatment of major depression.

As of 2013, ten second-generation antipsychotic drugs were approved by the Food and Drug Administration (FDA). These include the following: risperidone (Risperdal), risperidone IM long acting (Consta), olanzapine (Zyprexa), olanzapine for extended-release injectable suspension (Zyprexa Relprevv), quetiapine (Seroquel), quetiapine XR (Seroquel XR), ziprasidone (Geodon), aripiprazole (Abilify), paliperidone (Invega), paliperidone palmitate (Invega, Invega Sustenna), asenapine (Saphris), lurasidone (Latuda), iloperidone (Fanapt), and clozapine (Clozaril).

It is arguable whether the SDAs represent an improvement in overall tolerability than the DRAs. Although there is improvement with respect to a lowered, but not absent, risk of EPS, most of the drugs in this group often produce substantial weight gain, which in turn increases the potential for development of diabetes mellitus. Olanzapine and clozapine appear to account for most cases of weight gain and drug-induced diabetes mellitus. The other agents pose a smaller risk of these side effects; nevertheless, the FDA has requested that all SDAs carry a warning label that patients taking the drugs be monitored closely, and has recommended the following factors be considered for all
Patients prescribed second-generation antipsychotics.

1. Personal and family history of obesity, diabetes, dyslipidemia, hypertension, and cardiovascular disease
2. Weight and height (so that body mass index can be calculated)
3. Waist circumference (at the level of the umbilicus)
4. Blood pressure
5. Fasting plasma glucose level
6. Fasting lipid profile

Patients with preexisting diabetes should have regular monitoring, including hemoglobin A1C (HgA1C) and in some cases insulin levels. Among these drugs, clozapine sits apart. It is not considered a first-line agent because of side effects (hematological) and need for weekly blood tests. Although highly effective in treating both mania and depression, clozapine does not have an FDA indication for these conditions.

MECHANISMS OF ACTION

The presumed antipsychotic effects of the SDAs are blockade of D₂ dopamine receptors. Where the SDAs differ from older antipsychotic drugs is their higher ratio interactions with serotonin receptor subtypes, most notably the 5-HT2A subtype, as well as with other neurotransmitter systems. It is hypothesized that these properties account for the distinct tolerability profiles associated with each of the SDAs. All SDAs have different chemical structures, receptor affinities, and side effect profiles. No SDA is identical in its combination of receptor affinities, and the relative contribution of each receptor interaction to the clinical effects is unknown.

THERAPEUTIC INDICATIONS

Although initially approved for the treatment of schizophrenia and acute mania, some of these drugs have also been approved as adjunctive therapy in treatment-resistant depression and as adjunctive therapy in major depressive disorder. They are also useful in posttraumatic stress disorder and anxiety disorders, and although clinicians tend to use them in behavioral disturbances associated with dementia, all SDAs carry an FDA boxed warning regarding adverse effects when used in elderly persons with dementia-related psychoses, because elderly patients with dementia-related psychoses are at an increased risk (1.6 to 1.7 times) of death compared with placebo. All of these agents are considered first-line drugs for schizophrenia except clozapine, which may cause adverse hematological effects that require weekly blood sampling.

SCHIZOPHRENIA AND SCHIZOAFFECTIVE DISORDER

The SDAs are effective for treating acute and chronic psychoses such as schizophrenia
and schizoaffective disorder, in both adults and adolescents. SDAs are as good as or better than typical antipsychotics (DRAs) for the treatment of positive symptoms in schizophrenia and superior to DRAs for the treatment of negative symptoms. Compared with persons treated with DRAs, persons treated with SDAs have fewer relapses and require less frequent hospitalization, fewer emergency department visits, less phone contact with mental health professionals, and less treatment in day programs.

Because clozapine has potentially life-threatening adverse effects, it is appropriate only for patients with schizophrenia who are resistant to all other antipsychotics. Other indications for clozapine include treatment of persons with severe tardive dyskinesia—which can be reversed with high dosages in some cases—and those with a low threshold for EPS. Persons who tolerate clozapine have done well on long-term therapy. The effectiveness of clozapine may be increased by augmentation with risperidone, which raises clozapine concentrations and sometimes results in dramatic clinical improvement.

**Mood Disorders**

All of the SDAs (except clozapine) are FDA approved for treatment of acute mania. Some of these agents, including aripiprazole, olanzapine, quetiapine, and quetiapine XR, are also approved for the maintenance treatment in bipolar disorder as monotherapy or adjunctive therapy. The SDAs improve depressive symptoms in schizophrenia, and both clinical experience and clinical trials show that all of the SDAs augment antidepressants in the acute management of major depression. At this time, olanzapine in combination with fluoxetine has been approved for treatment-resistant depression, and aripiprazole and quetiapine XR are indicated for adjunctive therapy to antidepressants in major depressive disorders (MDDs). Quetiapine and quetiapine XR are also approved in bipolar depression. A fixed combination of olanzapine and fluoxetine (Symbyax) is approved as a treatment for acute bipolar depression.

**Other Indications**

About 10 percent of patients with schizophrenia exhibit outwardly aggressive or violent behavior, and the SDAs are effective for treatment of such aggression. Other off-label indications include acquired immunodeficiency syndrome (AIDS) dementia, autistic spectrum disorders, Tourette’s disorder, Huntington’s disease, and Lesch-Nyhan syndrome. Risperidone and olanzapine have been used to control aggression and self-injury in children. These drugs have also been coadministered with sympathomimetics, such as methylphenidate (Ritalin) or dextroamphetamine (Dexedrine), to children with attention-deficit/hyperactivity disorder who are comorbid for either oppositional–defiant disorder or conduct disorder. SDAs—especially olanzapine, quetiapine, and clozapine—are useful in persons who have severe tardive dyskinesia. The SDAs are also effective for treating psychotic depression and for psychosis secondary to head trauma, dementia, or treatment drugs.

Treatment with SDAs decreases the risk of suicide and water intoxication in patients with schizophrenia. Patients with treatment-resistant obsessive-compulsive disorder
(OCD) have responded to the SDAs; however, a few persons treated with the SDAs have been noted to develop treatment-emergent symptoms of OCD. Some patients with borderline personality disorder may improve with the SDAs.

Some data suggest that treatment with conventional DRAs has protective effects against the progression of schizophrenia when used during the first episode of psychosis. Ongoing studies are looking at whether the use of SDAs in at-risk patients with early evidence of disease prevents deterioration, thus improving long-term outcome.

**ADVERSE EFFECTS**

The SDAs share a similar spectrum of adverse reactions, but differ considerably in terms of frequency or severity of their occurrence. Specific side effects that are more common with an individual SDA are emphasized in the discussion of each drug in subsequent text.

**RISPERIDONE (Risperdal)**

**Indications**

Risperidone is indicated for the acute and maintenance treatment of schizophrenia in adults and for the treatment of schizophrenia in adolescents age 13 to 17 years. Risperidone is also indicated for the short-term treatment of acute manic or mixed episodes associated with bipolar I disorder in adults and in children and adolescents age 10 to 17 years. The combination of risperidone with lithium or valproate is indicated for the short-term treatment of acute manic or mixed episodes associated with bipolar I disorder.

Risperidone is also indicated for the treatment of irritability associated with autistic spectrum disorder in children and adolescents age 5 to 16 years, including symptoms of aggression toward others, deliberate self-injuriousness, temper tantrums, and quickly changing moods.

**Pharmacology**

Risperidone is a benzisoxazole. It undergoes extensive first-pass hepatic metabolism to 9-hydroxy risperidone, a metabolite with equivalent antipsychotic activity. Peak plasma levels of the parent compound occur within 1 hour for the parent compound and 3 hours for the metabolite. Risperidone has a bioactivity of 70 percent. The combined half-life of risperidone and 9-hydroxy risperidone averages 20 hours, so it is effective in once-daily dosing. Risperidone is an antagonist of the serotonin 5-HT$_{2A}$, dopamine D$_2$, $\alpha_1$-adrenergic and $\alpha_2$-adrenergic, and histamine H$_1$ receptors. It has a low affinity for $\alpha$-adrenergic and muscarinic cholinergic receptors. Although it is as potent an antagonist of D$_2$ receptors, as is haloperidol (Haldol), risperidone is much less likely than haloperidol to cause EPS in humans when the dose of risperidone is below 6 mg per day.
Dosages
The recommended dose range and frequency of risperidone dosing has changed since the drug first came into clinical use. Risperidone is available in 0.25, 0.5, 1, 2, 3, and 4 mg tablets and a 1 mg/mL oral solution. The initial dosage is usually 1 to 2 mg at night, which can then be increased to 4 mg per day. Positron emission tomography (PET) studies have shown that dosages of 1 to 4 mg per day provide the required D₄ blockade for a therapeutic effect. At first it was believed that because of its short elimination half-life, risperidone should be given twice a day, but studies have shown equal efficacy with once-a-day dosing. Dosages above 6 mg a day are associated with a higher incidence of adverse effects, particularly EPS. There is no correlation between plasma concentrations and therapeutic effect. Dosing guidelines for adolescents and children are different from those for adults, requiring lower starting dosages; higher dosages are associated with more adverse effects.

Side Effects
The EPS of risperidone are largely dosage dependent, and there has been a trend to using lower doses than initially recommended. Weight gain, anxiety, nausea and vomiting, rhinitis, erectile dysfunction, orgasmic dysfunction, and increased pigmentation are associated with risperidone use. The most common drug-related reasons for discontinuation of risperidone use are EPS, dizziness, hyperkinesias, somnolence, and nausea. Marked elevation of prolactin may occur. Weight gain occurs more commonly with risperidone use in children than in adults.

Risperidone is also available as an orally disintegrating tablet (Risperdal M-Tab), which is available in 0.5, 1, and 2 mg strengths, and in a depot formulation (Risperdal Consta), which is given as an intramuscular (IM) injection formulation every 2 weeks. The dose may be 25, 50, or 75 mg. Oral risperidone should be coadministered with Risperdal Consta for the first 3 weeks before being discontinued.

Drug Interactions
Inhibition of CYP2D6 by drugs such as paroxetine and fluoxetine can block the formation of risperidone's active metabolite. Risperidone is a weak inhibitor of CYP2D6 and has little effect on other drugs. Combined use of risperidone and selective serotonin reuptake inhibitors (SSRIs) may result in significant elevation of prolactin, with associated galactorrhea and breast enlargement.

PALIPERIDONE (INVEGA)
Indications
Paliperidone is indicated for the acute and maintenance treatment of schizophrenia. Paliperidone is also indicated for the acute treatment of schizoaffective disorder as monotherapy, or as an adjunct to mood stabilizers or antidepressants.
Pharmacology
Paliperidone is a benzisoxazole derivative and is the major active metabolite of risperidone. Peak plasma concentrations (C_{max}) are achieved approximately 24 hours after dosing, and steady-state concentrations of paliperidone are attained within 4 or 5 days. The hepatic isoenzymes CYP2D6 and CYP3A4 play a limited role in the metabolism and elimination of paliperidone, so no dose adjustment is required in patients with mild or moderate hepatic impairment.

Dosage
Paliperidone is available in 3, 6, and 9 mg tablets. The recommended dosage is 6 mg once daily administered in the morning. It can be taken with or without food. It is also available as extended-release tablets, which are also available in 3, 6, and 9 mg tablets administered once daily. It is recommended that no more than 12 mg should be administered per day. A long-acting formulation of paliperidone (Invega Sustenna) is given by injection once a month. Invega Sustenna is available as a white to off-white sterile aqueous extended-release suspension for intramuscular injection in dose strengths of 39 mg, 78 mg, 117 mg, 156 mg, and 234 mg paliperidone palmitate. The drug product hydrolyzes to the active moiety, paliperidone, resulting in dose strengths of 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg of paliperidone, respectively.

Invega Sustenna is provided in a prefilled syringe with a plunger stopper and tip cap. The kit also contains two safety needles (a 1 1/2-inch 22-gauge safety needle and a 1-inch 23 gauge safety needle). It has a half-life of 25 to 49 days. Monthly injections of 117 mg are recommended, although higher or lower dosages can be used depending on the clinical situation. The first two injections should be in the deltoid muscle because plasma concentrations are 28 percent higher with deltoid versus gluteal administration. Subsequent injections can alternate between gluteal and deltoid sites.

Side Effects
The dose of paliperidone should be reduced in patients with renal impairment. It may cause more sensitivity to temperature extremes such as very hot or cold conditions. Paliperidone may cause an increase in QT (QTc) interval and should be avoided in combination with other drugs that cause prolongation of QT interval. It may cause orthostatic hypotension, tachycardia, somnolence, akathisia, dystonia, EPS, and parkinsonism.

OLANZAPINE (ZYPREXA)
Indications
Olanzapine is indicated for the treatment of schizophrenia. Oral olanzapine is indicated for use as monotherapy for the acute treatment of manic or mixed episodes associated with bipolar I disorder and maintenance treatment of bipolar I disorder. Oral
Olanzapine is also indicated for the treatment of manic or mixed episodes associated with bipolar I disorder as an adjunct to lithium or valproate, and olanzapine can also be used in combination with fluoxetine (Symbyax) for the treatment of depressive episodes associated with bipolar I disorder.

Oral olanzapine and fluoxetine in combination (Symbyax) is indicated for the treatment of treatment-resistant depression. Olanzapine monotherapy is not indicated for the treatment of treatment-resistant depression.

**Pharmacology**

Approximately 85 percent of olanzapine is absorbed from the gastrointestinal (GI) tract, and about 40 percent of the dosage is inactivated by first-pass hepatic metabolism. Peak concentrations are reached in 5 hours, and the half-life averages 31 hours (range 21 to 54 hours). It is given in once-daily dosing. In addition to 5-HT\textsubscript{2A} and D\textsubscript{2} antagonism, olanzapine is an antagonist of the D\textsubscript{1}, D\textsubscript{4}, α\textsubscript{1}, 5-HT\textsubscript{1A}, muscarinic M\textsubscript{1} to M\textsubscript{5}, and H\textsubscript{1} receptors.

**Dosages**

Olanzapine is available in 2.5, 5, 7.5, 10, 15, and 20 mg oral and Zydis form (orally disintegrating) tablets. The initial dosage for treatment of psychosis is usually 5 or 10 mg, and for treatment of acute mania is usually 10 or 15 mg given once daily. It is also available as 5, 10, 15, and 20 mg orally disintegrating tablets that might be useful for patients who have difficulty swallowing pills or who “cheek” their medication.

A starting daily dose of 5 to 10 mg is recommended. After 1 week, the dosage can be raised to 10 mg a day. Given the long half-life, 1 week must be allowed to achieve each new steady-state blood level. Dosages in clinical use ranges vary, with 5 to 20 mg a day being most commonly used, but 30 to 40 mg a day being needed in treatment-resistant patients. A word of caution, however, is that the higher dosages are associated with increased EPS and other adverse effects, and dosages above 20 mg a day were not studied in the pivotal trials that led to the approval of olanzapine. The parenteral form of olanzapine is indicated for the treatment of acute agitation associated with schizophrenia and bipolar disorder, and the IM dosage is 10 mg. Coadministration with benzodiazepines is not approved.

**Other Formulations**

Olanzapine is available as an extended-release injectable suspension (Relprevv), which is a long-acting atypical IM injection indicated for the treatment of schizophrenia. It is injected deeply in the gluteal region and should not be administered intravenously or subcutaneously, nor is it approved for deltoid administration. Before administering the injection, the administrator should aspirate the syringe for several seconds to ensure that no blood is visible. It carries a boxed warning for postinjection delirium sedation.
syndrome (PDSS). Patients are at risk for severe sedation (including coma) and must be observed for 3 hours after each injection in a registered facility. In controlled studies, all patients with PDSS recovered, and there were no deaths reported. It is postulated that PDSS is secondary to increased levels of olanzapine secondary to accidental rupture of a blood vessel, causing extreme sedation or delirium. Patients should be managed as clinically appropriate and, if necessary, monitored in a facility capable of resuscitation. The injection can be given every 2 or 4 weeks depending on the dosing guidelines.

**Drug Interactions**
Fluvoxamine (Luvox) and cimetidine (Tagamet) increase, whereas carbamazepine and phenytoin decrease serum concentrations of olanzapine. Ethanol increases olanzapine absorption by more than 25 percent, leading to increased sedation. Olanzapine has little effect on the metabolism of other drugs.

**Side Effects**
Other than clozapine, olanzapine consistently causes a greater amount and more frequent weight gain than other atypicals. This effect is not dose related and continues over time. Clinical trial data suggest it peaks after 9 months, after which it may continue to increase more slowly. Somnolence, dry mouth, dizziness, constipation, dyspepsia, increased appetite, akathisia, and tremor are associated with olanzapine use. A small number of patients (2 percent) may need to discontinue use of the drug because of transaminase elevation. There is a dose-related risk of EPS. The manufacturer recommends “periodic” assessment of blood sugar and transaminases during treatment with olanzapine. There is an FDA-mandated warning about an increased risk of stroke among patients with dementia treated with SDAs, but this risk is small and is outweighed by improved behavioral control that treatment may produce.

**QUETIAPINE (SEROQUEL)**

**Indications**
Quetiapine is indicated for the treatment of schizophrenia, as well as the acute treatment of manic episodes associated with bipolar I disorder, both as monotherapy and as an adjunct to lithium or divalproex. It is also indicated as monotherapy for the acute treatment of depressive episodes associated with bipolar disorder and maintenance treatment of bipolar I disorder as an adjunct to lithium or divalproex.

**Pharmacology**
Quetiapine is a dibenzothiazepine structurally related to clozapine, but it differs markedly from that agent in biochemical effects. It is rapidly absorbed from the GI tract, with peak plasma concentrations reached in 1 to 2 hours. The steady-state half-life is about 7 hours, and optimal dosing is two or three times per day. Quetiapine, in addition
to being an antagonist of D₂ and 5-HT₂, also blocks 5-HT₆, D₁ and H₁, and α₁ and α₂ receptors. It does not block muscarinic or benzodiazepine receptors. The receptor antagonism for quetiapine is generally lower than that for other antipsychotic drugs, and it is not associated with EPS.

**Dosages**
Quetiapine is available in 25, 50, 100, 200, 300, and 400 mg tablets. Quetiapine dosing should begin at 25 mg twice daily, with doses then increased by 25 to 50 mg per dose every 2 to 3 days, up to a target of 300 to 400 mg a day. Studies have shown efficacy in the range of 300 to 800 mg a day. In reality, more aggressive dosing is both tolerated and more effective. It has become evident that the target dose can be achieved more rapidly, and that some patients benefit from dosages of as much as 1,200 to 1,600 mg a day. When used at higher doses, serial ECG studies are required. Despite its short elimination half-life, quetiapine can be given to many patients once a day. This is consistent with the observation that quetiapine receptor occupancy remains even when concentrations in the blood have markedly declined. Quetiapine in doses of 25 to 300 mg at night has been used for insomnia.

**Other Formulations**
Quetiapine XR has a comparable bioavailability to an equivalent dose of quetiapine administered two or three times daily. Quetiapine XR is given once daily, preferably in the evening 3 to 4 hours before bedtime without food or a light meal to prevent an increase in C_max. The usual starting dose is 300 mg, and it may be increased to 400 to 800 mg.

It has all of the above indications and in addition is indicated for use as adjunctive therapy to antidepressants for the treatment of MDD.

**Drug Interactions**
The potential interactions between quetiapine and other drugs have been well studied. Phenytoin increases quetiapine clearance fivefold; no major pharmacokinetic interactions have been noted. Avoid use of quetiapine with drugs that increase the QT interval and in patients with risk factors for prolonged QT interval. The FDA has added a new warning about quetiapine cautioning prescribers about potential prolongation of the QT interval when above-recommended amounts of quetiapine are combined with specific drugs. The use of quetiapine should be avoided in combination with other drugs that are known to prolong QTc including class 1A antiarrhythmics (e.g., quinidine, procainamide) or class III antiarrhythmics (e.g., amiodarone, sotalol), antipsychotic medications (e.g., ziprasidone, chlorpromazine, thioridazine), antibiotics (e.g., gatifloxacin, moxifloxacin), or any other class of medications known to prolong the QTc interval (e.g., pentamidine, levomethadyl acetate, methadone). Quetiapine should also
be avoided in circumstances that may increase the risk of occurrence of torsade de pointes and/or sudden death including (1) a history of cardiac arrhythmias such as bradycardia; (2) hypokalemia or hypomagnesemia; (3) concomitant use of other drugs that prolong the QTc interval; and (4) presence of congenital prolongation of the QT interval. Postmarketing cases also show increases in QT interval in patients who overdose on quetiapine.

**Side Effects**

Somnolence, postural hypotension, and dizziness are the most common adverse effects of quetiapine. These are usually transient and are best managed with initial gradual upward titration of the dosage. Quetiapine is the SDA least likely to cause EPS, regardless of dose. This makes it particularly useful in treating patients with Parkinson’s disease who develop dopamine agonist–induced psychosis. Prolactin elevation is rare and both transient and mild when it occurs. Quetiapine is associated with modest transient weight gain in some persons, but some patients occasionally gain a considerable amount of weight. The relationship between quetiapine and the development of diabetes is not as clearly established as are the cases involving the use of olanzapine. Small increases in heart rate, constipation, and a transient increase in liver transaminases may also occur. Initial concerns about cataract formation, based on animal studies, have not been borne out since the drug has been in clinical use. Nevertheless, it might be prudent to test for lens abnormalities early in treatment and periodically thereafter.

**ZIPRASIDONE (GEODON)**

**Indications**

Ziprasidone is indicated for the treatment of schizophrenia. Ziprasidone is also indicated as monotherapy for the acute treatment of manic or mixed episodes associated with bipolar I disorder and as an adjunct to lithium or valproate for the maintenance treatment of bipolar I disorder.

**Pharmacology**

Ziprasidone is a benzisothiazole piperazine. Peak plasma concentrations of ziprasidone are reached in 2 to 6 hours. Steady-state levels ranging from 5 to 10 hours are reached between the first and the third days of treatment. The mean terminal half-life at steady state ranges from 5 to 10 hours, which accounts for the recommendation that twice-daily dosing is necessary. Bioavailability doubles when ziprasidone is taken with food, and therefore it should be taken with food.

Peak serum concentrations of IM ziprasidone occur after approximately 1 hour, with a half-life of 2 to 5 hours.

Ziprasidone, similar to the other SDAs, blocks 5-HT_{2A} and D_{2} receptors. It is also an
antagonist of 5-HT\textsubscript{1D}, 5-HT\textsubscript{2C}, D\textsubscript{3}, D\textsubscript{4}, α\textsubscript{1}, and H\textsubscript{1} receptors. It has very low affinity for D\textsubscript{1}, M\textsubscript{1}, and α\textsubscript{2} receptors. In addition, ziprasidone has agonist activity at the serotonin 5-HT\textsubscript{1A} receptors and is an SSRI and a norepinephrine reuptake inhibitor. This is consistent with clinical reports that ziprasidone has antidepressant-like effects in nonschizophrenic patients.

**Dosages**

Ziprasidone is available in 20, 40, 60, and 80 mg capsules. Ziprasidone for IM use comes as a single-use 20 mg/mL vial. Oral ziprasidone dosing should be initiated at 40 mg a day divided into two daily doses. Studies have shown efficacy in the range of 80 to 160 mg a day, divided twice daily. In clinical practice, doses as high as 240 mg a day are being used. The recommended IM dosage is 10 to 20 mg every 2 hours for the 10 mg dose and every 4 hours for the 40 mg dose. The maximum total daily dose of IM ziprasidone is 40 mg.

Other than interactions with other drugs that prolong the QTc complex, ziprasidone appears to have low potential for clinically significant drug interactions.

**Side Effects**

Somnolence, headache, dizziness, nausea, and lightheadedness are the most common adverse effects in patients taking ziprasidone. It has almost no significant effects outside the central nervous system, is associated with almost no weight gain, and does not cause sustained prolactin elevation. Concerns about prolongation of the QTc complex have deterred some clinicians from using ziprasidone as a first choice. The QTc interval has been shown to increase in patients treated with 40 and 120 mg per day. Ziprasidone is contraindicated in combination with other drugs known to prolong the QTc interval. These include, but are not limited to, dofetilide, sotalol, quinidine, other class IA and III antiarrhythmics, mesoridazine, thioridazine, chlorpromazine, droperidol, pimozide, sparfloxacin, gatifloxacin, moxifloxacin, halofantrine, mefloquine, pentamidine, arsenic trioxide, levomethadyl acetate, dolasetron mesylate, probucol, and tacrolimus. Ziprasidone should be avoided in patients with congenital long QT syndrome and in patients with a history of cardiac arrhythmias.

**Aripiprazole (Abilify)**

Aripiprazole is a potent 5-HT\textsubscript{2A} antagonist and is indicated for the treatment of both schizophrenia and acute mania. It is also approved for augmentation of antidepressant agents in MDD. Aripiprazole is a D\textsubscript{2} antagonist, but can also act as a partial D\textsubscript{2} agonist. Partial D\textsubscript{2} agonists compete at D\textsubscript{2} receptors for endogenous dopamine, thereby producing a functional reduction of dopamine activity.
Indications
Aripiprazole is indicated for the treatment of schizophrenia. Short-term, 4- to 6-week studies comparing aripiprazole with haloperidol and risperidone in patients with schizophrenia and schizoaffective disorder have shown comparable efficacy. Dosages of 15, 20, and 30 mg a day were found to be effective. Long-term studies suggest that aripiprazole is effective as a maintenance treatment at a daily dose of 15 to 30 mg.

Aripiprazole is also indicated for the acute and maintenance treatment of manic and mixed episodes associated with bipolar I disorder. It is also used as an adjunctive therapy to either lithium or valproate for the acute treatment of manic and mixed episodes associated with bipolar I disorder.

Aripiprazole is indicated for use as an adjunctive therapy to antidepressants for the treatment of MDD. Aripiprazole is also indicated for the treatment of irritability associated with autistic disorder.

Pharmacology
Aripiprazole is well absorbed, reaching peak plasma concentrations after 3 to 5 hours. Absorption is not affected by food. The mean elimination half-life of aripiprazole is about 75 hours. It has a weakly active metabolite with a half-life of 96 hours. These relatively long half-lives make aripiprazole suitable for once-daily dosing. Clearance is reduced in elderly persons. Aripiprazole exhibits linear pharmacokinetics and is primarily metabolized by CYP3A4 and CYP2D6 enzymes. It is 99 percent protein bound. Aripiprazole is excreted in breast milk in lactating rats.

Mechanistically, aripiprazole acts as a modulator, rather than a blocker, and acts on both postsynaptic D<sub>2</sub> receptors and presynaptic autoreceptors. In theory, this mechanism addresses excessive limbic dopamine (hyperdopaminergic) activity, and decreased dopamine (hypodopaminergic) activity in frontal and prefrontal areas—abnormalities that are thought to be present in schizophrenia. The absence of complete D<sub>2</sub> blockade in the striatal areas would be expected to minimize EPS. Aripiprazole is an α<sub>1</sub>-adrenergic receptor antagonist, which may cause some patients to experience orthostatic hypotension. Similar to the so-called atypical antipsychotic agents, aripiprazole is a 5-HT<sub>2A</sub> antagonist.

Other Uses
A study of aggressive children and adolescents with oppositional defiant disorder or conduct disorder found that there was a positive response in about 60 percent of the subjects. In this study, vomiting and somnolence led to a reduction in initial aripiprazole dosage.

Drug Interactions
Whereas carbamazepine and valproate reduce serum concentrations, ketoconazole, fluoxetine, paroxetine, and quinidine increase aripiprazole serum concentrations. Lithium and valproic acid, two drugs likely to be combined with aripiprazole when treating bipolar disorder, do not affect the steady-state concentrations of aripiprazole. Combined use with antihypertensives may cause hypotension. Drugs that inhibit CYP2D6 activity reduce aripiprazole elimination.

**Dosage and Clinical Guidelines**

Aripiprazole is available as 5, 10, 15, 20, and 30 mg tablets. The effective dosage range is 10 to 30 mg per day. Although the starting dosage is 10 to 15 mg per day, problems with nausea, insomnia, and akathisia have led to use of lower than recommended starting dosages of aripiprazole. Many clinicians find that an initial dose of 5 mg increases tolerability.

**Side Effects**

The most commonly reported side effects of aripiprazole are headache, somnolence, agitation, dyspepsia, anxiety, and nausea. Although it is not a frequent cause of EPS, aripiprazole does cause akathisia-like activation. Described as restlessness or agitation, it can be highly distressing and often leads to discontinuation of medication. Insomnia is another common complaint. Data so far do not indicate that weight gain or diabetes mellitus have an increased incidence with aripiprazole (Abilify). Prolactin elevation does not typically occur. Aripiprazole does not cause significant QTc interval changes. There have been reports of seizures.

**ASENAPINE (SAPHRIS)**

**Indications**

Asenapine is approved for the acute treatment of adults with schizophrenia and acute treatment of manic or mixed episodes associated with bipolar I disorder with or without psychotic features in adults.

**Pharmacology**

Asenapine has an affinity for several receptors, including serotonin (5-HT2A and 5-HT2C), noradrenergic (α₂ and α₁), dopaminergic (D3 and D4 receptors is higher than its affinity for D2 receptors), and histamine (H1). It has negligible affinity for muscarinic-1 cholinergic receptors and hence less incidence of dry mouth, blurred vision, constipation, and urinary retention. The bioavailability is 35 percent via sublingual (preferred) route and it achieves peak plasma concentration in 1 hour. Asenapine is metabolized through glucuronidation and oxidative metabolism by CYP1A2, so coadministration with fluvoxamine and other CYP1A2 inhibitors should be done cautiously.
**Dosage**

Asenapine is available as 5 mg and 10 mg sublingual tablets, and should be placed under the tongue. This is because the bioavailability of asenapine is less than 2 percent when swallowed, but is 35 percent when absorbed sublingually. The agent dissolves in saliva within seconds and is absorbed through the oral mucosa. Sublingual administration avoids first-pass hepatic metabolism. Patients should be advised to avoid drinking or eating for 10 minutes after taking asenapine because this may lower the blood levels. The recommended starting and target dose for schizophrenia is 5 mg twice a day. In bipolar disorder, the patient may be started on 10 mg twice a day, and if necessary, the dosage may be lowered to 5 mg twice a day depending on the tolerability issues. In acute schizophrenia treatment there is no evidence of added benefit with a 10 mg twice-daily dose, but there is a clear increase in certain adverse reactions. In both bipolar I disorder and schizophrenia, the maximum dose should not exceed 10 mg two times a day. The safety of doses above 10 mg twice a day has not been evaluated in clinical studies.

**Side Effects**

The most common side effects observed in schizophrenic and bipolar disorders are somnolence, dizziness, EPS other than akathisia, and increased weight. In clinical trials, the mean weight gain after 52 weeks is 0.9 kg, and there were no clinically relevant differences in lipid profile and blood glucose after 52 weeks. In clinical trials, asenapine was found to increase the QTc interval in a range of 2 to 5 milliseconds compared to placebo. No patients treated with asenapine experienced QTc increases 60 milliseconds or greater from baseline measurements, nor did any experience a QTc of 500 milliseconds or more. Nevertheless, asenapine should be avoided in combination with other drugs known to prolong QTc interval, in patients with congenital prolongation of QT interval or a history of cardiac arrhythmias, and in circumstances that may increase the occurrence of torsades de pointes. Asenapine can increase prolactin levels, and the elevation can persist during chronic administration. Galactorrhea, amenorrhea, gynecomastia, and impotence may occur.

**CLOZAPINE (CLOZARIL)**

**Indications**

In addition to being the most effective drug treatment for patients who have failed to respond to standard therapies, clozapine has been shown to benefit patients with severe tardive dyskinesia. Clozapine suppresses these dyskinesias, but the abnormal movements return when clozapine is discontinued. This is true even though clozapine, on rare occasions, may cause tardive dyskinesia. Other clinical situations in which clozapine may be used include the treatment of psychotic patients who are intolerant of EPS caused by other agents, treatment-resistant mania, severe psychotic depression,
idiopathic Parkinson’s disease, Huntington’s disease, and suicidal patients with schizophrenia or schizoaffective disorder. Other treatment-resistant disorders that have demonstrated response to clozapine include pervasive developmental disorder, autism of childhood, and OCD (either alone or in combination with an SSRI). Used by itself, clozapine may very rarely induce obsessive-compulsive symptoms.

Pharmacology
Clozapine is a dibenzothiazepine. It is rapidly absorbed, with peak plasma levels reached in about 2 hours. Steady state is achieved in less than 1 week if twice daily dosing is used. The elimination half-life is about 12 hours. Clozapine has two major metabolites, one of which, N-dimethyl clozapine, may have some pharmacological activities. Clozapine is an antagonist of 5-HT$_2A$, D$_1$, D$_3$, D$_4$, and α (especially α$_1$) receptors. It has relatively low potency as a D$_2$ receptor antagonist. Data from PET scanning show that whereas 10 mg of haloperidol produces 80 percent occupancy of striatal D$_2$ receptors, clinically effective dosages of clozapine occupy only 40 to 50 percent of striatal D$_2$ receptors. This difference in D$_2$ receptor occupancy is probably why clozapine does not cause EPS. It has also been postulated that clozapine and other SDAs bind more loosely to the D$_2$ receptor, and because of this “fast dissociation,” more normal dopamine neurotransmission is possible.

Dosages
Clozapine is available in 25 mg and 100 mg tablets. The initial dosage is usually 25 mg one or two times daily, although a conservative initial dosage is 12.5 mg twice daily. The dosage can then be increased gradually (25 mg a day every 2 or 3 days) to 300 mg a day in divided doses, usually two or three times a day. Dosages up to 900 mg a day can be used. Testing for blood concentrations of clozapine may be helpful in patients who fail to respond. Studies have found that plasma concentrations greater than 350 μg/mL are associated with a better likelihood of response.

Drug Interactions
Clozapine should not be used with any other drug that is associated with the development of agranulocytosis or bone marrow suppression. Such drugs include carbamazepine, phenytoin, propylthiouracil, sulfonamides, and captopril (Capoten). Lithium combined with clozapine may increase the risk of seizures, confusion, and movement disorders. Lithium should not be used in combination with clozapine by persons who have experienced an episode of neuroleptic malignant syndrome. Clomipramine (Anafranil) can increase the risk of seizure by lowering the seizure threshold and by increasing clozapine plasma concentrations. Risperidone, fluoxetine, paroxetine, and fluvoxamine increase serum concentrations of clozapine. Addition of paroxetine may precipitate clozapine-associated neutropenia.
**Side Effects**

The most common drug-related adverse effects are sedation, dizziness, syncope, tachycardia, hypotension, electrocardiography (ECG) changes, nausea, and vomiting. Other common adverse effects include fatigue, weight gain, various GI symptoms (most commonly constipation), anticholinergic effects, and subjective muscle weakness. Sialorrhea, or hypersalivation, is a side effect that begins early in treatment and is most evident at night. Patients report that their pillows are drenched with saliva. This side effect is most likely the result of impairment of swallowing. Although there are reports that clonidine or amitriptyline may help reduce hypersalivation, the most practical solution is to put a towel over the pillow.

The risk of seizures is about 4 percent in patients taking dosages greater than 600 mg a day. Leukopenia, granulocytopenia, agranulocytosis, and fever occur in about 1 percent of patients. During the first year of treatment, there is a 0.73 percent risk of clozapine-induced agranulocytosis. The risk during the second year is 0.07 percent. For neutropenia, the risk is 2.32 percent and 0.69 percent, respectively, during the first and second years of treatment. The only contraindications to the use of clozapine are a white blood cell (WBC) count below 3,500 cells per mm$^3$; a previous bone marrow disorder; a history of agranulocytosis during clozapine treatment; or the use of another drug that is known to suppress the bone marrow, such as carbamazepine (Tegretol).

During the first 6 months of treatment, weekly WBC counts are indicated to monitor the patient for the development of agranulocytosis. If the WBC count remains normal, the frequency of testing can be decreased to every 2 weeks. Although monitoring is expensive, early indication of agranulocytosis can prevent a fatal outcome. Clozapine should be discontinued if the WBC count is below 3,000 cells per mm$^3$ or the granulocyte count is below 1,500 per mm$^3$. In addition, a hematological consultation should be obtained, and obtaining bone marrow sample should be considered. Persons with agranulocytosis should not be re-exposed to the drug. To avoid situations in which a physician or a patient fails to comply with the required blood tests, clozapine cannot be dispensed without proof of monitoring.

Patients exhibiting symptoms of chest pain, shortness of breath, fever, or tachypnea should be immediately evaluated for myocarditis or cardiomyopathy, an infrequent but serious adverse effect ending in death. Serial CPK-MB (creatine phosphokinase with myocardial band fractions), troponin levels, and EKG studies are recommended, with immediate discontinuation of clozapine.

**ILOPERIDONE (FANAPT)**

**Indications**

Iloperidone (Fanapt) is indicated for the acute treatment of schizophrenia in adults. The safety and efficacy of iloperidone in children and adolescents has not been established.
Pharmacology
Iloperidone is not a derivative of another antipsychotic agent. It has complex multiple antagonist effects on several neurotransmitter systems. Iloperidone has a strong affinity for dopamine D$\textsubscript{3}$ receptors, followed by decreasing affinities of $\alpha_{2c}$-noradrenergic, 5-HT$\textsubscript{1a}$, D$\textsubscript{2a}$, and 5-HT$\textsubscript{6}$ receptors. Iloperidone has a low affinity for histaminergic receptors. As with other antipsychotics, the clinical significance of this receptor binding affinity is unknown.

Iloperidone has a peak concentration of 2 to 4 hours and a half-life that is dependent on hepatic isoenzyme metabolism. It is metabolized primarily through CYP2D6 and CYP3A4, and the dosage should be reduced by half when administered concomitantly with strong inhibitors of these two isoenzymes. The half-life is 18 to 26 hours in CYP2D6 extensive metabolizers and is 31 to 37 hours in CYP2D6 poor metabolizers. Of note, approximately 7 to 10 percent of whites and 3 to 8 percent of African Americans lack the capacity to metabolize CYP2D6 substrates; hence, dosing should be determined with this caveat in mind. Iloperidone should be used with caution in persons with severe hepatic impairment.

Side Effects
Iloperidone prolongs the QT interval and may be associated with arrhythmia and sudden death. Iloperidone prolongs the QTc interval by 9 milliseconds at dosages of 12 mg twice daily. Concurrent use with other agents that prolong the QTc interval may result in additive effects on the QTc interval. The concurrent use of iloperidone with agents that prolong the QTc interval may result in potentially life-threatening cardiac arrhythmias, including torsades de pointes. Concurrent administration of other drugs that are known to prolong the QTc interval should be avoided. Cardiovascular disease, hypokalemia, hypomagnesemia, bradycardia, congenital prolongation of the QT interval, and concurrent use of inhibitors of CYP3A4 or CYP2D6, which metabolize iloperidone, may increase the risk of QT prolongation.

The most common adverse effects reported are dizziness, dry mouth, fatigue, sedation, tachycardia, and orthostatic hypotension (depending on dosing and titration). Despite being a strong D$\textsubscript{2}$ antagonist, the rates of EPS and akathisia are similar to those of placebo. The mean weight gain in short-term and long-term trials is 2.1 kg. Due to its relatively limited use, there is no accurate understanding of iloperidone’s effects on weight and lipids. Some patients exhibit elevated prolactin levels. Three cases of priapism have been reported in the premarketing phase.

Dosing
Iloperidone must be titrated slowly to avoid orthostatic hypotension. It is available in a titration pack, and the effective dose (12 mg) should be reached in approximately 4 days based on a twice-a-day dosing schedule. It is usually started on day 1 at 1 mg twice
a day and increased daily on a twice-a-day schedule to reach 12 mg by day 4. The maximum recommended dose is 12 mg twice a day (24 mg a day), and it can be administered without regard to food.

LURASIDONE HCL (LATUDA)

Indications
Lurasidone hydrochloride is an oral, once-daily atypical antipsychotic indicated for the treatment of patients with schizophrenia. To date there has not been extensive clinical experience with lurasidone.

Side Effects
The most commonly observed adverse reactions associated with the use of lurasidone are similar to those seen with other new-generation antipsychotics. These include, but are not limited to somnolence, akathisia, nausea, parkinsonism, and agitation. Based on clinical trial data, lurasidone appears to cause less weight gain and metabolic changes than the two other most recently approved SDAs, asenapine and iloperidone. More extensive clinical experience with the drug is required to determine whether this is in fact the case.

Drug Interactions
When coadministration of lurasidone with a moderate CYP3A4 inhibitor such as diltiazem is considered, the dose should not exceed 40 mg per day. Lurasidone should not be used in combination with a strong CYP3A4 inhibitor (e.g., ketoconazole). Lurasidone also should not be used in combination with a strong CYP3A4 inducer (e.g., rifampin).

Dosages
Lurasidone is available as 20, 40, 80, and 120 mg tablets. Initial dose titration is not required. The recommended starting dose is 40 mg once daily, and the medication should be taken with food. It has been shown to be effective in a dose range of 40 to 120 mg per day. Although there is no proven added benefit with the 120 mg per day dose, there may be a dose-related increase in adverse reactions. Still, some patients may benefit from the maximum recommended dose of 160 mg per day. Dose adjustment is recommended in patients with renal impairment. The dose in moderate to severe renal impairment should not exceed 80 mg per day. The dose in severe hepatic impairment patients should not exceed 40 mg per day.

CLINICAL GUIDELINES FOR SDAS
All SDAs are appropriate for the management of an initial psychotic episode, but
clozapine is reserved for persons who are refractory to all other antipsychotic drugs. If a
person does not respond to the first SDA, other SDAs should be tried. The choice of drug
should be based on the patient’s clinical status and history of response to medication.
Recent studies have challenged the notion that SDAs require 4 to 6 weeks to reach full
effectiveness, and it may take up to 8 weeks for the full clinical effects of an SDA toecome apparent. The newer meta-analyses suggest that the apparent benefits may be
seen as early as 2 to 3 weeks, and early response or failure is an indicator of subsequent
response or failure. Nevertheless, it is acceptable practice to augment an SDA with a
high-potency DRA or benzodiazepine in the first few weeks of use. Lorazepam (Ativan)
1 to 2 mg orally or IM can be used as needed for acute agitation. Once effective,
dosages can be lowered as tolerated. Clinical improvement may take 6 months of
treatment with SDAs in some particularly treatment-refractory persons.

Use of all SDAs must be initiated at low dosages and gradually tapered upward to
therapeutic dosages. The gradual increase in dosage is necessitated by the potential
development of adverse effects. If a person stops taking an SDA for more than 36 hours,
drug use should be resumed at the initial titration schedule. After the decision to
terminate olanzapine or clozapine use, dosages should be tapered whenever possible to
avoid cholinergic rebound symptoms such as diaphoresis, flushing, diarrhea, and
hyperactivity.

After a clinician has determined that a trial of an SDA is warranted for a particular
person, the risks and benefits of SDA treatment must be explained to the person and the
family. In the case of clozapine, an informed consent procedure should be documented
in the person’s chart. The patient’s history should include information about blood
disorders, epilepsy, cardiovascular disease, hepatic and renal diseases, and drug abuse.
The presence of a hepatic or renal disease necessitates using low starting dosages of the
drug. The physical examination should include supine and standing blood pressure
measurements to screen for orthostatic hypotension. The laboratory examination should
include an ECG and several complete blood counts with WBC counts, which can then be
averaged; and liver and renal function tests. Periodic monitoring of blood glucose,
lipids, and body weight is recommended.

Although the transition from a DRA to an SDA may be made abruptly, it is wiser to
taper off the DRA slowly while titrating up the SDA. Clozapine and olanzapine both
have anticholinergic effects, and the transition from one to the other can usually be
accomplished with little risk of cholinergic rebound. The transition from risperidone
to olanzapine is best accomplished by tapering the risperidone off over 3 weeks while
simultaneously beginning olanzapine at 10 mg a day. Risperidone, quetiapine, and
ziprasidone lack anticholinergic effects, and the abrupt transition from a DRA,
olanzapine, or clozapine to one of these agents may cause cholinergic rebound, which
consists of excessive salivation, nausea, vomiting, and diarrhea. The risk of cholinergic
rebound can be mitigated by initially augmenting risperidone, quetiapine, or
ziprasidone with an anticholinergic drug, which is then tapered off slowly. Any
initiation and termination of SDA use should be accomplished gradually.

It is wise to overlap administration of the new drug with the old drug. Of interest,
some people have a more robust clinical response while taking the two agents during
the transition and then regressing on monotherapy with the newer drug. Little is known
about the effectiveness and safety of a strategy of combining one SDA with another SDA
or with a DRA.

Persons receiving regular injections of depot formulations of a DRA who are to switch
to SDA use are given the first dose of the SDA on the day the next injection is due.

Persons who developed agranulocytosis while taking clozapine can safely switch to
olanzapine use, although initiation of olanzapine use in the midst of clozapine-induced
agranulocytosis can prolong the time of recovery from the usual 3 to 4 days up to 11 to
12 days. It is prudent to wait for resolution of agranulocytosis before initiating
olanzapine use. Emergence or recurrence of agranulocytosis has not been reported with
olanzapine, even in persons who developed it while taking clozapine.

SDA use by pregnant women has not been studied, but consideration should be given
to the potential of risperidone to raise prolactin concentrations, sometimes up to three
to four times the upper limit of the normal range. Because the drugs can be excreted in
breast milk, they should not be taken by nursing mothers. The dosages for selected SDAs
are given in Table 29.29-1.

Table 29.29-1
Comparison of Usual Dosing\textsuperscript{a} for Some Available Second-generation
Antipsychotics in Schizophrenia
REFERENCES

Stimulant drugs increase motivation, mood, energy, and wakefulness. They are also called sympathomimetics, because they mimic the physiological effects of the neurotransmitter epinephrine. Several chemical classes are included in this group.

Currently these drugs are most commonly used to treat symptoms of poor concentration and hyperactivity in children and adults with attention-deficit/hyperactivity disorder (ADHD). Paradoxically, many patients with ADHD find that these drugs can have a calming effect. Sympathomimetics are also approved for use in increasing alertness in narcolepsy.

Amphetamines were the first stimulants to be synthesized. They were created in the late 19th century and were used by Bavarian soldiers in the mid-1880s to maintain wakefulness, alertness, energy, and confidence in combat. They have been used in a similar fashion in most wars since then. They were not widely used clinically until the 1930s, when they were marketed as Benzedrine inhalers for relief of nasal congestion. When their psychostimulant effects were noted, these drugs were used to treat sleepiness associated with narcolepsy. They have been classified as controlled drugs because of their rapid onset, immediate behavioral effects, and propensity to develop tolerance, which leads to the risk of abuse and dependence in vulnerable individuals. Their manufacture, distribution, and use are regulated by state and federal agencies. In 2005, pemoline was withdrawn from the market because of significant risks of treatment-emergent hepatotoxicity.

Sympathomimetics have been widely used in persons with ADHD and narcolepsy because no equally effective agents have been available. They have also been found effective in treating certain cognitive disorders that result in secondary depression or profound apathy (e.g., acquired immunodeficiency syndrome [AIDS], multiple sclerosis, poststroke depression and dementia, closed head injury) as well as in the augmentation of antidepressant medications in specific treatment-resistant depressions.

Atomoxetine is included in this section because it is used to treat ADHD, even though it is not a psychostimulant.

**PHARMACOLOGICAL ACTIONS**

All of these drugs are well absorbed from the gastrointestinal tract. Amphetamine (Adderall) and dextroamphetamine (Dexedrine, Dextrostat) reach peak plasma concentrations in 2 to 3 hours and have a half-life of about 6 hours, thereby
Methylphenidate is available in immediate-release (Ritalin), sustained-release (Ritalin SR), and extended-release (Concerta, Quillivant XR) formulations. Immediate-release methylphenidate reaches peak plasma concentrations in 1 to 2 hours and has a short half-life of 2 to 3 hours, thereby necessitating multiple-daily dosing. The sustained-release formulation reaches peak plasma concentrations in 4 to 5 hours and doubles the effective half-life of methylphenidate. The extended-release formulation reaches peak plasma concentrations in 6 to 8 hours and is designed to be effective for 12 hours in once-daily dosing. Dexmethylphenidate (Focalin) reaches peak plasma concentration in about 3 hours and is prescribed twice daily.

Lisdexamfetamine dimesylate, also known as 1-lysine-d-amphetamine (Vyvanse), is an amphetamine prodrug. In this formulation, dextroamphetamine is coupled with the amino acid 1-lysine. Lisdexamfetamine becomes active upon cleavage of the lysine portion of the molecule by enzymes in the red blood cells. This results in the gradual release of dextroamphetamine into the bloodstream. Apart from having an extended duration of action, this type of formulation reduces its abuse potential. It is the only prodrug of its kind. Lisdexamfetamine is indicated for the treatment of ADHD in children 6 to 12 years and in adults as an integral part of a total treatment program that may include other measures (i.e., psychological, educational, social). The safety and efficacy of lisdexamfetamine dimesylate in patients 3 to 5 years old has not been established. In contrast to Adderall, which contains approximately 75 percent dextroamphetamine and 25 percent levoamphetamine, lisdexamfetamine is a single, dextro-enantiomer amphetamine molecule. In most cases this makes the drug better tolerated, but there are some patients who experience greater benefit from the mixed isomer preparation.

Methylphenidate, dextroamphetamine, and amphetamine are indirectly acting sympathomimetics, with the primary effect causing the release of catecholamines from presynaptic neurons. Their clinical effectiveness is associated with increased release of both dopamine and norepinephrine. Dextroamphetamine and methylphenidate are also weak inhibitors of catecholamine reuptake and inhibitors of monoamine oxidase.

For modafinil, the specific mechanism of action is unknown. Narcolepsy–cataplexy results from deficiency of hypocretin, a hypothalamic neuropeptide. Hypocretin-producing neurons are activated after modafinil administration. Modafinil does not appear to work through a dopaminergic mechanism. It does have $\alpha_1$-adrenergic agonist properties, which may account for its alerting effects, because the wakefulness induced by modafinil can be attenuated by prazosin, an $\alpha_1$-adrenergic antagonist. Some evidence suggests that modafinil has some norepinephrine reuptake blocking effects. Armodafinil (Nuvigil) is the R-enantiomer of modafinil. Both drugs have similar clinical effects and side effects.

THERAPEUTIC INDICATIONS
**Attention-Deficit/Hyperactivity Disorder (ADHD)**

Sympathomimetics are the first-line drugs for treatment of ADHD in children and are effective about 75 percent of the time. Methylphenidate and dextroamphetamine are equally effective and work within 15 to 30 minutes. Pemoline (Cylert) requires 3 to 4 weeks to reach its full efficacy; however, because of toxicity, it is rarely used. Sympathomimetic drugs decrease hyperactivity, increase attentiveness, and reduce impulsivity. They may also reduce comorbid oppositional behaviors associated with ADHD. Many persons take these drugs throughout their schooling and beyond. In responsive persons, use of a sympathomimetic may be a critical determinant of scholastic success.

Sympathomimetics improve the core ADHD symptoms of hyperactivity, impulsivity, and inattentiveness and permit improved social interactions with teachers, family, other adults, and peers. The success of long-term treatment of ADHD with sympathomimetics, which are efficacious for most of the various constellations of ADHD symptoms present from childhood to adulthood, supports a model in which ADHD results from a genetically determined neurochemical imbalance that requires lifelong pharmacologic management.

Methylphenidate is the most commonly used initial agent, at a dosage of 5 to 10 mg every 3 to 4 hours. Dosages may be increased to a maximum of 20 mg four times daily or 1 mg/kg a day. Use of the 20 mg sustained-release formulation to achieve 6 hours of benefit and eliminate the need for dosing at school is supported by many experts, although other authorities believe it is less effective than the immediate-release formulation. Dextroamphetamine is about twice as potent as methylphenidate on a per milligram basis and provides 6 to 8 hours of benefit. Some 70 percent of nonresponders to one sympathomimetic may benefit from another. All of the sympathomimetic drugs should be tried before switching to drugs of a different class. The previous dictum that sympathomimetics worsen tics and therefore should be avoided by persons with comorbid ADHD and tic disorders has been questioned. Small dosages of sympathomimetics do not appear to cause an increase in the frequency and severity of tics. Alternatives to sympathomimetics for ADHD include bupropion (Wellbutrin), venlafaxine (Effexor), guanfacine (Tenex), clonidine (Catapres), and tricyclic drugs. Further studies are needed to determine whether modafinil improves the symptoms of ADHD.

Short-term use of the sympathomimetics induces a euphoric feeling; however, tolerance develops for both the euphoric feeling and the sympathomimetic activity.

**Narcolepsy and Hypersomnolence**

Narcolepsy consists of sudden sleep attacks (*narcolepsy*), sudden loss of postural tone (*cataplexy*), loss of voluntary motor control going into (hypnagogic) or coming out of (hypnopompic) sleep (*sleep paralysis*), and hypnagogic or hypnopompic hallucinations. Sympathomimetics reduce narcoleptic sleep attacks and improve wakefulness in other types of hypersomnolent states. Modafinil is approved as an antisuomnia agent for
Treatment of narcolepsy, for people who cannot adjust to night shift work, and for those who do not sleep well because of obstructive sleep apnea.

Other sympathomimetics are also used to maintain wakefulness and accuracy of motor performance in persons subject to sleep deprivation, such as pilots and military personnel. Persons with narcolepsy, unlike persons with ADHD, may develop tolerance for the therapeutic effects of the sympathomimetics.

In direct comparison with amphetamine-like drugs, modafinil is equally effective at maintaining wakefulness, with a lower risk of excessive activation.

**Depressive Disorders**

Sympathomimetics may be used for treatment-resistant depressive disorders, usually as augmentation of standard antidepressant drug therapy. Possible indications for use of sympathomimetics as monotherapy include depression in elderly persons, who are at increased risk for adverse effects from standard antidepressant drugs; depression in medically ill persons, especially persons with AIDS; obtundation caused by chronic use of opioids; and clinical situations in which a rapid response is important but for which electroconvulsive therapy is contraindicated. Depressed patients with abulia and anergia may also benefit.

Dextroamphetamine may be useful in differentiating pseudodementia of depression from dementia. A depressed person generally responds to a 5 mg dose with increased alertness and improved cognition. Sympathomimetics are thought to provide only short-term benefit (2 to 4 weeks) for depression, because most persons rapidly develop tolerance for the antidepressant effects of the drugs. However, some clinicians report that long-term treatment with sympathomimetics can benefit some persons.

**Encephalopathy Caused by Brain Injury**

Sympathomimetics increase alertness, cognition, motivation, and motor performance in persons with neurological deficits caused by strokes, trauma, tumors, or chronic infections. Treatment with sympathomimetics may permit earlier and more robust participation in rehabilitative programs. Poststroke lethargy and apathy may respond to long-term use of sympathomimetics.

**Obesity**

Sympathomimetics are used in the treatment of obesity because of their anorexia-inducing effects. Because tolerance develops for the anorectic effects and because of the drugs’ high abuse potential, their use for this indication is limited. Of the sympathomimetic drugs, phentermine (Adipex-P, Fastin) is the most widely used for appetite suppression. Phentermine was the second half of “fen-phen,” an off-label combination of fenfluramine and phentermine, widely used to promote weight loss until fenfluramine and dexfenfluramine were withdrawn from commercial availability because of an association with cardiac valvular insufficiency, primary pulmonary
hypertension, and irreversible loss of cerebral serotoninergic nerve fibers. The toxicity of fenfluramine is attributed to the fact that it stimulates release of massive amounts of serotonin from nerve endings, a mechanism of action not shared by phentermine. Use of phentermine alone has not been reported to cause the same adverse effects as those caused by fenfluramine or dexfenfluramine.

Careful limitation of caloric intake and judicious exercise are at the core of any successful weight loss program. Sympathomimetic drugs facilitate loss of, at most, an additional fraction of a pound per week. Sympathomimetic drugs are effective appetite suppressants only for the first few weeks of use; then the anorexigenic effects tend to decrease.

**Fatigue**

Between 70 and 90 percent of individuals with multiple sclerosis experience fatigue. Modafinil, armodafinil, amphetamines, methylphenidate, and the dopamine receptor agonist amantadine (Symmetrel) are sometimes effective in combating this symptom. Other causes of fatigue such as chronic fatigue syndrome respond to stimulants in many cases.

**PRECAUTIONS AND ADVERSE REACTIONS**

The most common adverse effects associated with amphetamine-like drugs are stomach pain, anxiety, irritability, insomnia, tachycardia, cardiac arrhythmias, and dysphoria. Sympathomimetics cause a decreased appetite, although tolerance usually develops for this effect. The treatment of common adverse effects in children with ADHD is usually straightforward (Table 29.30-1). The drugs can also cause increases in heart rate and blood pressure and may cause palpitations. Less common adverse effects include the possible induction of movement disorders, such as tics, Tourette’s disorder–like symptoms, and dyskinesias, all of which are often self-limited over 7 to 10 days. If a person taking a sympathomimetic develops one of these movement disorders, a correlation between the dose of the medication and the severity of the disorder must be firmly established before adjustments are made in the medication dosage. In severe cases, augmentation with risperidone (Risperdal), clonidine (Catapres), or guanfacine (Tenex) is necessary. Methylphenidate may worsen tics in one-third of persons; these persons fall into two groups: those whose methylphenidate-induced tics resolve immediately upon metabolism of the dosage and a smaller group in whom methylphenidate appears to trigger tics that persist for several months but eventually resolve spontaneously.

---

**Table 29.30-1**

Management of Common Stimulant-induced Adverse Effects in Attention-deficit/Hyperactivity Disorder
Longitudinal studies do not indicate that sympathomimetics cause growth suppression. Sympathomimetics may exacerbate glaucoma, hypertension, cardiovascular disorders, hyperthyroidism, anxiety disorders, psychotic disorders, and seizure disorders. High dosages of sympathomimetics can cause dry mouth, pupillary dilation, bruxism, formication, excessive ebullience, restlessness, emotional lability, and occasionally seizures. Long-term use of high dosages can cause a delusional disorder that resembles paranoid schizophrenia. Seizures can be treated with benzodiazepines, cardiac effects with β-adrenergic receptor antagonists, fever with cooling blankets, and delirium with dopamine receptor antagonists (DRAs). Overdosages of sympathomimetics result in hypertension, tachycardia, hyperthermia, toxic psychosis, delirium, hyperpyrexia, convulsions, coma, chest pain, arrhythmia, heart block, hypertension or hypotension, shock, and nausea. Toxic effects of amphetamines can be seen at 30 mg, but idiosyncratic toxicity can occur at doses as low as 2 mg. Conversely, survival has been reported up to 500 mg.

The most limiting adverse effect of sympathomimetics is their association with psychological and physical dependence. At the doses used for treatment of ADHD, development of psychological dependence virtually never occurs. A larger concern is the presence of adolescent or adult cohabitants who might confiscate the supply of sympathomimetics for abuse or sale.

The use of sympathomimetics should be avoided during pregnancy, especially during...
the first trimester. Dextroamphetamine and methylphenidate pass into the breast milk, and it is not known whether modafinil or armodafinil do.

**DRUG INTERACTIONS**

The coadministration of sympathomimetics and tricyclic or tetracyclic antidepressants, warfarin (Coumadin), primidone (Mysoline), phenobarbital (Luminal), phenytoin (Dilantin), or phenylbutazone (Butazolidin) decreases the metabolism of these compounds, resulting in increased plasma levels. Sympathomimetics decrease the therapeutic efficacy of many antihypertensive drugs, especially guanethidine (Esimil, Ismelin). The sympathomimetics should be used with extreme caution with monoamine oxidase inhibitors (MAOIs).

**LABORATORY INTERFERENCES**

Dextroamphetamine may elevate plasma corticosteroid levels and interfere with some assay methods for urinary corticosteroids.

**DOSAGE AND ADMINISTRATION**

Many psychiatrists believe that amphetamine use has been overly regulated by governmental authorities. Amphetamines are listed as schedule II drugs by the Drug Enforcement Agency. Some states keep a registry of patients who receive amphetamines. Such mandates worry both patients and physicians about breaches in confidentiality, and physicians are concerned that their prescribing practices may be misinterpreted by official agencies. Consequently, some physicians may withhold prescription of sympathomimetics, even from persons who may benefit from the medications.

The dosage ranges and the available preparations for sympathomimetics are presented in Table 29.30-2. Vyvanse dosing is a special case, because many patients are switched to this formulation after being treated with other stimulants. A conversion table is shown in Table 29.30-3. It is available in 20, 30, 40, 50, 60, and 70 mg capsules. Dosage should be individualized according to the therapeutic needs and response of the patient. Lisdexamfetamine (Vyvanse) should be administered at the lowest effective dosage. In patients who are either starting treatment for the first time or switching from another medication, 30 mg once daily in the morning is the recommended dose. Dosages may go up or down in 10 mg or 20 mg increments in intervals of approximately 1 week. Afternoon doses should be avoided because of the potential for insomnia. The drug may be taken with or without food.

| Table 29.30-2 |
| Sympathomimetics Commonly Used in Psychiatry |
Dextroamphetamine, methylphenidate, amphetamine, benzphetamine, and methamphetamine are schedule II drugs and in some states require triplicate prescriptions. Phendimetrazine (Adipost, Bontril) and phenmetrazine (Prelude) are schedule III drugs, and modafinil, armodafinil, phentermine, diethylpropion (Tenuate), and mazindol (Mazanor, Sanorex) are schedule IV drugs.

Pretreatment evaluation should include an evaluation of the patient’s cardiac function, with particular attention to the presence of hypertension or tachyarrhythmias.

XR, extended release; IR, immediate-release.
The clinician should also examine the patient for the presence of movement disorders, such as tics and dyskinesia, because these conditions can be exacerbated by the administration of sympathomimetics. If tics are present, many experts will not prescribe sympathomimetics but will instead choose clonidine or antidepressants. However, recent data indicate that sympathomimetics may cause only a mild increase in motor tics and may actually suppress vocal tics. Liver function and renal function should be assessed, and dosages of sympathomimetics should be reduced for persons with impaired metabolism.

Persons with ADHD can take immediate-release methylphenidate at 8 am, 12 noon, and 4 pm. Dextroamphetamine, Adderall, sustained-release methylphenidate, or 18 mg of extended-release methylphenidate may be taken once at 8 am. The starting dose of methylphenidate ranges from 2.5 mg of regular to 20 mg of the sustained-release formulation. If this is inadequate, it may be increased to a maximum dose of 80 mg in children and 90 mg daily in adults. The dosage of dextroamphetamine is 2.5 to 40 mg a day up to 0.5 mg/kg a day.

Quillivant XR (methylphenidate hydrochloride) is a once-daily, extended-release liquid formulation of methylphenidate HCL. Quillivant XR is supplied as a liquid solution designed for oral administration and is taken once a day. The recommended dose for patients 6 years and older is 20 mg orally once daily in the morning with or without food. The dose may be titrated weekly in increments of 10 mg to 20 mg. Daily doses above 60 mg have not been studied and are not recommended. Before administering the dose, vigorously shake the bottle of Quillivant XR for at least 10 seconds, to ensure that the proper dose is administered. The clinical effects of the drug are evident from 45 minutes to 12 hours after dosing.

The starting dosage of modafinil is 200 mg in the morning in medically healthy individuals and 100 mg in the morning in persons with hepatic impairment. Some persons take a second 100 mg or 200 mg dose in the afternoon. The maximum recommended daily dosage is 400 mg, although dosages of 600 to 1,200 mg a day have been used safely. Adverse effects become prominent at dosages greater than 400 mg a day. Compared with amphetamine-like drugs, modafinil promotes wakefulness but produces less attentiveness and less irritability. Some persons with excessive daytime sleepiness extend the activity of the morning modafinil dose with an afternoon dose of methylphenidate. Armodafinil is virtually identical to modafinil, but is dosed differently, the dosing range being 50–250 mg daily.

**ATOMOXETINE (STRATTERA)**

Atomoxetine is the first nonstimulant drug to be approved by the Food and Drug Administration (FDA) as a treatment of ADHD in children, adolescents, and adults. It is included in this chapter because it shares this indication with the stimulants described earlier.

**Pharmacological Actions**
Atomoxetine is believed to produce a therapeutic effect through selective inhibition of the presynaptic norepinephrine transporter. It is well absorbed after oral administration and is minimally affected by food. High-fat meals may decrease the rate but not the extent of absorption. Maximum plasma concentrations are reached after approximately 1 to 2 hours. At therapeutic concentrations, 98 percent of atomoxetine in plasma is bound to protein, mainly albumin. Atomoxetine has a half-life of approximately 5 hours and is metabolized principally by the cytochrome P450 (CYP)2D6 pathway. Poor metabolizers of this compound reach a fivefold higher area under the curve and fivefold higher peak plasma concentration than normal or extensive metabolizers. This is important to consider in patients receiving medications that inhibit the CYP2D6 enzyme. For example, the antidepressant-like pharmacology of atomoxetine has led to its use as an add-on to selective serotonin reuptake inhibitors (SSRIs) or other antidepressants. Drugs such as fluoxetine (Prozac), paroxetine (Paxil), and bupropion (Wellbutrin) are CYP2D6 inhibitors and may raise atomoxetine levels.

**Therapeutic Indications**

Atomoxetine is used for the treatment of ADHD. It should be considered for use in patients who find stimulants too activating or who experience other intolerable side effects. Because atomoxetine has no abuse potential, it is a reasonable choice in the treatment of patients with both ADHD and substance abuse, patients who complain of ADHD symptoms but are suspected of seeking stimulant drugs, and patients who are in recovery.

Atomoxetine may enhance cognition when used to treat patients with schizophrenia. It may also be used as an alternative or add-on to antidepressants in patients who fail to respond to standard therapies.

**Precautions and Adverse Reactions**

Common side effects of atomoxetine include abdominal discomfort, decreased appetite with resulting weight loss, sexual dysfunction, dizziness, vertigo, irritability, and mood swings. Minor increases in blood pressure and heart rate have also been observed. There have been cases of severe liver injury in a small number of patients taking atomoxetine. The drug should be discontinued in patients with jaundice (yellowing of the skin or whites of the eyes, itching) or laboratory evidence of liver injury. Atomoxetine should not be taken at the same time as, or within 2 weeks of taking, an MAOI or by patients with narrow-angle glaucoma.

The effects of overdose greater than twice the maximum recommended daily dose in humans are unknown. No specific information is available on the treatment of overdose with atomoxetine.

**Dosage and Clinical Guidelines**

Atomoxetine is available as 10, 18, 25, 40, and 60 mg capsules. In children and
adolescents who weigh up to 70 kg, atomoxetine should be initiated at a total daily dose of approximately 0.5 mg/kg and increased after a minimum of 3 days to a target total daily dose of approximately 1.2 mg/kg, administered either as a single daily dose in the morning or as evenly divided doses in the morning and late afternoon or early evening. The total daily dose in smaller children and adolescents should not exceed 1.4 mg/kg or 100 mg, whichever is less. Dosing of children and adolescents who weigh more than 70 kg and adults should start at a total daily dose of 40 mg and then be increased after a minimum of 3 days to a target total daily dose of approximately 80 mg. The doses can be administered either as a single daily dose in the morning or as evenly divided doses in the morning and late afternoon or early evening. After 2 to 4 additional weeks, the dose may be increased to a maximum of 100 mg in patients who have not achieved an optimal response. The maximum recommended total daily dose in children and adolescents over 70 kg and adults is 100 mg.

REFERENCES
Thyroid hormones—levothyroxine (Synthroid, Levothroid, Levoxine) and liothyronine (Cytomel)—are used in psychiatry either alone or as augmentation to treat persons with depression or rapid-cycling bipolar I disorder. They can convert an antidepressant-nonresponsive person into an antidepressant-responsive person. Thyroid hormones are also used as replacement therapy for persons treated with lithium (Eskalith) who have developed a hypothyroid state. Successful use of thyroid hormone as an intervention for treatment-resistant patients was first reported in the early 1970s. Study results since then have been mixed; however, most show that patients taking triiodothyronine ($T_3$) are twice as likely to respond to antidepressant treatment versus placebo. These studies have found that augmentation with $T_3$ is effective with tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRIs). Nevertheless, many endocrinologists object to the use of thyroid hormones as antidepressant augmentation agents, citing such risks as osteoporosis and cardiac arrhythmias.

### 29.31 Thyroid Hormones

Thyroid hormones are administered orally, and their absorption from the gastrointestinal tract is variable. Absorption is increased if the drug is administered on
an empty stomach. Thyroxine (T_4) crosses the blood–brain barrier and diffuses into neurons, where it is converted into T_3, which is the physiologically active form. The half-life of T_4 is 6 to 7 days, and that of T_3 is 1 to 2 days.

The mechanism of action for thyroid hormone effects on antidepressant efficacy is unknown. Thyroid hormone binds to intracellular receptors that regulate the transcription of a wide range of genes, including several receptors for neurotransmitters.

**THERAPEUTIC INDICATIONS**

The major indication for thyroid hormones in psychiatry is as an adjuvant to antidepressants. There is no clear correlation between the laboratory measures of thyroid function and the response to thyroid hormone supplementation of antidepressants. If a patient has not responded to a 6-week course of antidepressants at appropriate dosages, adjuvant therapy with either lithium or a thyroid hormone is an alternative. Most clinicians use adjuvant lithium before trying a thyroid hormone. Several controlled trials have indicated that liothyronine use converts about 50 percent of antidepressant nonresponders to responders.

The dosage of liothyronine is 25 or 50 μg a day added to the patient’s antidepressant regimen. Liothyronine has been used primarily as an adjuvant for tricyclic drugs; however, evidence suggests that liothyronine augments the effects of all of the antidepressant drugs.

Thyroid hormones have not been shown to cause particular problems in pediatric or geriatric patients; however, the hormones should be used with caution in elderly persons, who may have occult heart disease.

**PRECAUTIONS AND ADVERSE REACTIONS**

At the dosages usually used for augmentation—25 to 50 μg a day—adverse effects occur infrequently. The most common adverse effects associated with thyroid hormones are transient headache, weight loss, palpitations, nervousness, diarrhea, abdominal cramps, sweating, tachycardia, increased blood pressure, tremors, and insomnia. Osteoporosis may also occur with long-term treatment, but this has not been found in studies involving liothyronine augmentation. Overdoses of thyroid hormones can lead to cardiac failure and death.

Thyroid hormones should not be taken by persons with cardiac disease, angina, or hypertension. The hormones are contraindicated in thyrotoxicosis and uncorrected adrenal insufficiency and in persons with acute myocardial infarctions. Thyroid hormones can be administered safely to pregnant women, provided that laboratory thyroid indexes are monitored. Thyroid hormones are minimally excreted in breast milk and have not been shown to cause problems in nursing babies.

**DRUG INTERACTIONS**
Thyroid hormones can potentiate the effects of warfarin (Coumadin) and other anticoagulants by increasing the catabolism of clotting factors. They may increase the insulin requirement for diabetic persons and the digitalis requirement for persons with cardiac disease. Thyroid hormones should not be coadministered with sympathomimetics, ketamine (Ketalar), or maprotiline (Ludiomil) because of the risk of cardiac decompensation. Administration of SSRI s, tricyclic and tetracyclic drugs, lithium, or carbamazepine (Tegretol) can mildly lower serum T$_4$ and raise serum thyrotropin concentrations in euthyroid persons or persons taking thyroid replacements. This interaction warrants close serum monitoring and may require an increase in the dosage or initiation of thyroid hormone supplementation.

LABORATORY INTERFERENCES
Levothyroxine has not been reported to interfere with any laboratory test other than thyroid function indexes. Liothyronine, however, suppresses the release of endogenous T$_4$, thereby lowering the result of any thyroid function test that depends on the measure of T$_4$.

THYROID FUNCTION TESTS
Several thyroid function tests are available, including tests for T$_4$ by competitive protein binding (T$_4$ [D]) and by radioimmunoassay (T$_4$ RIA) involving a specific antigen–antibody reaction. More than 90 percent of T$_4$ is bound to serum protein and is responsible for thyroid-stimulating hormone (TSH) secretion and cellular metabolism. Other thyroid measures include the free T$_4$ index (FT$_4$), T$_3$ uptake, and total serum T$_3$ measured by radioimmunoassay (T$_3$ RIA). Those tests are used to rule out hypothyroidism, which can be associated with symptoms of depression. In some studies, up to 10% of patients complaining of depression and associated fatigue had incipient hypothyroid disease. Lithium can cause hypothyroidism and, more rarely, hyperthyroidism. Neonatal hypothyroidism results in intellectual disability and is preventable if the diagnosis is made at birth.

Thyrotropin-releasing Hormone Stimulation Test
The thyrotropin-releasing hormone (TRH) stimulation test is indicated for patients who have marginally abnormal thyroid test results with suspected subclinical hypothyroidism, which may account for clinical depression. It is also used in patients with possible lithium-induced hypothyroidism. The procedure entails an intravenous injection of 500 mg of protirelin (TRH), which produces a sharp increase in serum TSH levels are measured at 15, 30, 60, and 90 minutes. An increase in serum TSH of 5 to 25 mIU/mL above the baseline is normal. An increase of less than 7 mIU/mL is considered a blunted response, which may correlate with a diagnosis of depression. Eight percent of
all patients with depression have some thyroid illness.

**DOSAGE AND CLINICAL GUIDELINES**

Liothyronine is available in 5, 25, and 50 μg tablets. Levothyroxine is available in 12.5, 25, 50, 75, 88, 100, 112, 125, 150, 175, 200, and 300 μg tablets; it is also available in a 200 and 500 μg parenteral form. The dosage of liothyronine is 25 or 50 μg a day added to the person’s antidepressant regimen. Liothyronine has been used as an adjuvant for all of the available antidepressant drugs. An adequate trial of liothyronine supplementation should last 2 to 3 weeks. If liothyronine supplementation is successful, it should be continued for 2 months and then tapered off at a rate of 12.5 μg a day every 3 to 7 days.

29.32 Tricyclics and Tetracyclics

The observation in 1957 that imipramine (Tofranil) had antidepressant effects led to the development of a new class of antidepressant compounds, the tricyclics (TCAs). In turn, the finding that imipramine blocked reuptake of norepinephrine led to research into the role of catecholamines in depression. After the introduction of imipramine, several other antidepressant compounds were developed that shared a basic tricyclic structure and had relatively similar effects. Later, other heterocyclic compounds were also marketed that were somewhat similar in structure and that had relatively comparable secondary properties. At one time, amitriptyline (Elavil, Endep) and imipramine were the two most commonly prescribed antidepressants in the United States, but because of their anticholinergic and antihistaminic side effects, their use declined, and nortriptyline (Aventyl, Pamelor) and desipramine (Norpramin, Pertofrane) became more popular. Nortriptyline has the least effect on orthostatic hypotension, and desipramine is the least anticholinergic. Although introduced as antidepressants, the therapeutic indications for these agents have grown to include panic disorder, GAD, PTSD, OCD, and pain syndromes. The introduction of newer antidepressant agents with more selective actions on neurotransmitters or with unique mechanisms of action has sharply reduced the prescribing of TCAs and tetracyclics. The improved safety profiles of the newer drugs, especially when taken in overdose, also contributed to the decline in use of the older drugs. Nevertheless, the TCAs and tetracyclics remain unsurpassed in terms of their antidepressant efficacy. Table 29.32-1 lists TCA and tetracyclic drugs and their available preparations.

PHARMACOLOGIC ACTIONS

The absorption of most TCAs is complete after oral administration, and there is significant metabolism from the first-pass effect. Peak plasma concentrations occur within 2 to 8 hours, and the half-lives of the TCAs vary from 10 to 70 hours;
nortriptyline, maprotiline (Ludiomil), and particularly protriptyline (Vivactil) can have longer half-lives. The long half-lives allow all the compounds to be given once daily; 5 to 7 days is needed to reach steady-state plasma concentrations. Imipramine pamoate (Tofranil) is a depot form of the drug for intramuscular (IM) administration; indications for the use of this preparation are limited.

The TCAs undergo hepatic metabolism by the CYP450 enzyme system. Clinically relevant drug interactions may result from competition for enzyme CYP2D6 among TCAs and quinidine, cimetidine (Tagamet), fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), phenothiazines, carbamazepine (Tegretol), and the type IC antiarrhythmics propafenone (Rythmol) and flecainide (Tambocor). Concomitant administration of TCAs and these inhibitors may slow down the metabolism and raise the plasma concentrations of TCAs. Additionally, genetic variations in the activity of CYP2D6 may account for up to a 40-fold difference in plasma TCA concentrations in different persons. The dosage of the TCA may need to be adjusted to correct changes in the rate of hepatic TCA metabolism.

The TCAs block the transporter site for norepinephrine and serotonin, thus increasing synaptic concentrations of these neurotransmitters. Each drug differs in its affinity for each of these transporters, with clomipramine (Anafranil) being the most serotonin selective and desipramine the most norepinephrine selective of the TCAs. Secondary effects of the TCAs include antagonism at the muscarinic acetylcholine, histamine H₁, and α₁- and α₂-adrenergic receptors. The potency of these effects on other receptors largely determines the side effect profile of each drug. Amoxapine, nortriptyline, desipramine, and maprotiline have the least anticholinergic activity; doxepin has the most antihistaminergic activity. Although they are more likely to cause constipation, sedation, dry mouth, or lightheadedness than the SSRIs, the TCAs are less prone to cause sexual dysfunction, significant long-term weight gain, and sleep disturbances than the SSRIs. The half-lives and plasma clearance for most TCAs are very similar.

**THERAPEUTIC INDICATIONS**

Each of the following indications is also an indication for the SSRIs, which have widely replaced the TCAs in clinical practice. However, the TCAs represent a reasonable alternative for persons who cannot tolerate the adverse effects of the SSRIs.

**Major Depressive Disorder**

The treatment of a major depressive episode and the prophylactic treatment of major depressive disorder are the principal indications for using TCAs. Although the TCAs are effective in the treatment of depression in persons with bipolar I disorder, they are more likely to induce mania, hypomania, or cycling than the newer antidepressants, most notably the SSRIs and bupropion. It is thus not advised that TCAs be routinely used to treat depression associated with bipolar I or bipolar II disorder. Melancholic features, prior major depressive episodes, and a family history of
depressive disorders increase the likelihood of a therapeutic response. All of the available TCAs are equally effective in the treatment of depressive disorders. In the case of an individual person, however, one tricyclic or tetracyclic may be effective, and another one may be ineffective. The treatment of a major depressive episode with psychotic features almost always requires the coadministration of an antipsychotic drug and an antidepressant.

Although it is used worldwide as an antidepressant, clomipramine is only approved in the United States for the treatment of OCD.

**Panic Disorder with Agoraphobia**

Imipramine is the TCA most studied for panic disorder with agoraphobia, but other TCAs are also effective when taken at the usual antidepressant dosages. Because of the potential initial anxiogenic effects of the TCAs, starting dosages should be small, and the dosage should be titrated upward slowly. Small doses of benzodiazepines may be used initially to deal with this side effect.

**Generalized Anxiety Disorder**

The use of doxepin for the treatment of anxiety disorders is approved by the FDA. Some research data show that imipramine may also be useful. Although rarely used anymore, a chlordiazepoxide–amitriptyline combination (Limbitrol) is available for mixed anxiety and depressive disorders.

**Obsessive-Compulsive Disorder**

Patients with OCD appear to respond specifically to clomipramine, as well as the SSRIs. Some improvement is usually seen in 2 to 4 weeks, but a further reduction in symptoms may continue for the first 4 to 5 months of treatment. None of the other TCAs appears to be nearly as effective as clomipramine for treatment of this disorder. Clomipramine may also be a drug of choice for depressed persons with marked obsessive features.

**Pain**

The TCAs are widely used to treat chronic neuropathic pain and in prophylaxis of migraine headache. Amitriptyline is the TCA most often used in this role. During treatment of pain, doses are generally lower than those used in depression; for example, 75 mg of amitriptyline may be effective. These effects also appear more rapidly.

**Other Disorders**

Childhood enuresis is often treated with imipramine. Peptic ulcer disease can be treated with doxepin, which has marked antihistaminergic effects. Other indications for the TCAs are narcolepsy, nightmare disorder, and PTSD. The drugs are sometimes used for treatment of children and adolescents with ADHD, sleepwalking disorder, separation
anxiety disorder, and sleep terror disorder. Clomipramine has also been used to treat premature ejaculation, movement disorders, and compulsive behavior in children with autistic disorders; however, because the TCAs have caused sudden death in several children and adolescents, they should not be used in children.

PRECAUTIONS AND ADVERSE REACTIONS
The TCAs are associated with a wide range of problematic side effects and can be lethal when taken in overdose.

Psychiatric Effects
The TCAs can induce a switch to mania or hypomania in susceptible individuals. The TCAs may also exacerbate psychotic disorders in susceptible persons. At high plasma concentrations (levels above 300 ng/mL), the anticholinergic effects of the TCAs can cause confusion or delirium. Patients with dementia are particularly vulnerable to this development.

Anticholinergic Effects
Anticholinergic effects often limit the tolerable dosage to relatively low ranges. Some persons may develop a tolerance for the anticholinergic effects with continued treatment. Anticholinergic effects include dry mouth, constipation, blurred vision, delirium, and urinary retention. Sugarless gum, candy, or fluoride lozenges can alleviate dry mouth. Bethanechol (Urecholine), 25 to 50 mg three or four times a day, may reduce urinary hesitancy and may be helpful in erectile dysfunction when the drug is taken 30 minutes before sexual intercourse. Narrow-angle glaucoma can also be aggravated by anticholinergic drugs, and the precipitation of glaucoma requires emergency treatment with a miotic agent. The TCAs should be avoided in persons with narrow-angle glaucoma, and an SSRI should be substituted. Severe anticholinergic effects can lead to a CNS anticholinergic syndrome with confusion and delirium, especially if the TCAs are administered with dopamine receptor antagonists (DRAs) or anticholinergic drugs. IM or IV physostigmine (Antilirium, Eserine) is used to diagnose and treat anticholinergic delirium.

Cardiac Effects
When administered in their usual therapeutic dosages, the TCAs may cause tachycardia, flattened T waves, prolonged QT intervals, and depressed ST segments in the electrocardiographic (EKG) recording. Imipramine has a quinidine-like effect at therapeutic plasma concentrations and may reduce the number of premature ventricular contractions. Because the drugs prolong conduction time, their use in persons with preexisting conduction defects is contraindicated. In persons with a history of any type of heart disease, the TCAs should be used only after SSRIs or other newer antidepressants have been found ineffective, and if used, they should be introduced at
low dosages, with gradual increases in dosage and monitoring of cardiac functions. All of the TCAs can cause tachycardia, which may persist for months and is one of the most common reasons for drug discontinuation, especially in younger persons. At high plasma concentrations, as seen in overdoses, the drugs become arrhythmogenic.

**Other Autonomic Effects**

Orthostatic hypotension is the most common cardiovascular autonomic adverse effect and the most common reason TCAs are discontinued. It can result in falls and injuries in affected persons. Nortriptyline may be the drug least likely to cause this problem. Orthostatic hypotension is treated with avoidance of caffeine, intake of at least 2 L of fluid per day and addition of salt to the diet unless the person is being treated for hypertension. In persons taking antihypertensive agents, reduction of the dosage may reduce the risk of orthostatic hypotension. Other possible autonomic effects are profuse sweating, palpitations, and increased blood pressure (BP). Although some persons respond to fludrocortisone (Florinef), 0.02 to 0.05 mg twice a day, substitution of an SSRI is preferable to addition of a potentially toxic mineralocorticoid such as fludrocortisone. The TCAs’ use should be discontinued several days before elective surgery because of the occurrence of hypertensive episodes during surgery in persons receiving TCAs.

**Sedation**

Sedation is a common effect of the TCAs and may be welcomed if sleeplessness has been a problem. The sedative effect of the TCAs is a result of anticholinergic and antihistaminergic activities. Amitriptyline, trimipramine, and doxepin are the most sedating agents; imipramine, amoxapine, nortriptyline, and maprotiline are less sedating; and desipramine and protriptyline are the least sedating agents.

**Neurologic Effects**

A fine, rapid tremor may occur. Myoclonic twitches and tremors of the tongue and the upper extremities are common. Rare effects include speech blockage, paresthesia, peroneal palsies, and ataxia.

Amoxapine is unique in causing parkinsonian symptoms, akathisia, and even dyskinesia because of the dopaminergic blocking activity of one of its metabolites. Amoxapine may also cause neuroleptic malignant syndrome in rare cases. Maprotiline may cause seizures when the dosage is increased too quickly or is kept at high levels for too long. Clomipramine and amoxapine may lower the seizure threshold more than other drugs in the class. As a class, however, the TCAs have a relatively low risk for inducing seizures except in persons who are at risk for seizures (e.g., persons with epilepsy and those with brain lesions). Although the TCAs can still be used by such persons, the initial dosages should be lower than usual, and subsequent dosage increases should be gradual.
Allergic and Hematologic Effects
Exanthematous rashes are seen in 4 to 5 percent of all persons treated with maprotiline. Jaundice is rare. Agranulocytosis, leukocytosis, leukopenia, and eosinophilia are rare complications of TCA treatment. However, a person who has a sore throat or a fever during the first few months of TCA treatment should have a complete blood count (CBC) done immediately.

Hepatic Effects
Mild and self-limited increases in serum transaminase concentrations may occur and should be monitored. The TCAs can also produce a fulminant acute hepatitis in 0.1 to 1 percent of persons. This can be life threatening, and the antidepressant should be discontinued.

Other Adverse Effects
Modest weight gain is common. Amoxapine exerts a DRA effect and may cause hyperprolactinemia, impotence, galactorrhea, anorgasmia, and ejaculatory disturbances. Other TCAs have also been associated with gynecomastia and amenorrhea. The syndrome of inappropriate secretion of antidiuretic hormone has also been reported with TCAs. Other effects include nausea, vomiting, and hepatitis.

Teratogenicity and Pregnancy-Related Risks. A definitive link between the tricyclic compounds and tetracyclic compounds and teratogenic effects has not been established, but isolated reports of morphogenesis have been reported. TCAs cross the placenta, and neonatal drug withdrawal can occur. This syndrome includes tachypnea, cyanosis, irritability, and poor sucking reflex. If possible, tricyclic and tetracyclic medications should be discontinued 1 week before delivery. Recently, norepinephrine and serotonin transporters have been identified in the placenta and appear to play an important role in the clearance of these amines in the fetus. The understanding of the effects of reuptake inhibitors on these transporters during pregnancy is limited, but one study compared intelligence and language development in 80 children exposed to TCAs during pregnancy with 84 children exposed to other nonteratogenic agents and found no deleterious effects of the TCAs. The TCAs are excreted in breast milk at concentrations similar to plasma. The actual quantity delivered, however, is small, so drug levels in the infant are usually undetectable or very low. Because the risk of relapse is a serious concern in patients with recurrent depression, and these risks may be increased during pregnancy or the postpartum period, the risks and benefits of continuing or withdrawing treatment need to be discussed with the patient and weighed carefully.

Precautions
The TCAs may cause a withdrawal syndrome in newborns consisting of tachypnea, cyanosis, irritability, and poor sucking reflex. The drugs do pass into breast milk but at concentrations that are usually undetectable in the infant’s plasma. The drugs should be used with caution in persons with hepatic and renal diseases. The TCAs should not be administered during a course of electroconvulsive therapy, primarily because of the risk of serious adverse cardiac effects.

**DRUG INTERACTIONS**

**Monoamine Oxidase Inhibitors**
The TCAs should not be taken within 14 days of administration of an MAOI.

**Antihypertensives**
The TCAs block the therapeutic effects of antihypertensive medication. The antihypertensive effects of the β-adrenergic receptor antagonists (e.g., propranolol [Inderal] and clonidine [Catapres]) may be blocked by the TCAs. The coadministration of a TCA and α-methyldopa (Aldomet) may cause behavioral agitation.

**Antiarrhythmic Drugs**
The antiarrhythmic properties of TCAs can be additive to those of quinidine, an effect that is further exacerbated by the inhibition of TCA metabolism by quinidine.

**Dopamine Receptor Antagonists**
Concurrent administration of TCAs and DRAs increases the plasma concentrations of both drugs. Desipramine plasma concentrations may increase twofold during concurrent administration with perphenazine (Trilafon). The DRAs also add to the anticholinergic and sedative effects of the TCAs. Concomitant use of serotonin–dopamine antagonists (SDAs) also increase those effects.

**Central Nervous System Depressants**
Opioids, alcohol, anxiolytics, hypnotics, and over-the-counter cold medications have additive effects by causing CNS depression when coadministered with TCAs. Persons should be advised to avoid driving or using dangerous equipment if sedated by TCAs.

**Sympathomimetics**
Tricyclic drug use with sympathomimetic drugs may cause serious cardiovascular effects.

**Oral Contraceptives**
Birth control pills may decrease TCA plasma concentrations through the induction of
hepatic enzymes.

**Other Drug Interactions**

Nicotine may reduce TCA concentrations. Plasma concentrations may also be lowered by ascorbic acid, ammonium chloride, barbiturates, cigarette smoking, carbamazepine, chloral hydrate, lithium (Eskalith), and primidone (Mysoline). TCA plasma concentrations may be increased by concurrent use of acetazolamide (Diamox), sodium bicarbonate, acetylsalicylic acid, cimetidine, thiazide diuretics, fluoxetine, paroxetine, and fluvoxamine (Luvox). Plasma concentrations of the TCAs may rise three- to fourfold when administered concurrently with fluoxetine, fluvoxamine, and paroxetine.

**LABORATORY INTERFERENCES**

The tricyclic compounds are present at low concentrations and are not likely to interfere with other laboratory assays. It is possible that they may interfere with the determination of conventional neuroleptic blood concentrations because of their structural similarity and the low concentrations of some neuroleptics.

**DOSAGE AND CLINICAL GUIDELINES**

Persons who intend to take TCAs should undergo routine physical and laboratory examinations, including a CBC, a white blood cell count with differential, and serum electrolytes with liver function tests. An EKG should be obtained for all persons, especially women older than 40 years of age and men older than 30 years of age. The TCAs are contraindicated in persons with a QT$_C$ greater than 450 milliseconds. The initial dose should be small and should be raised gradually. Because of the availability of highly effective alternatives to TCAs, a newer agent should be used if there is any medical condition that may interact adversely with the TCAs.

Elderly persons and children are more sensitive to TCA adverse effects than are young adults. In children, the EKG should be regularly monitored during use of a TCA.

The available preparations of TCAs are presented in Table 29.32-1. The dosages and therapeutic blood levels for the TCAs vary among the drugs (Table 29.32-2). With the exception of protriptyline, all of the TCAs should be started at 25 mg a day and increased as tolerated. Divided doses at first reduce the severity of the adverse effects, although most of the dosage should be given at night to help induce sleep if a sedating drug such as amitriptyline is used. Eventually, the entire daily dose can be given at bedtime. A common clinical mistake is to stop increasing the dosage when the person is tolerating the drug but taking less than the maximum therapeutic dose and does not show clinical improvement. The clinician should routinely assess the person’s pulse and orthostatic changes in BP while the dosage is being increased.
Nortriptyline use should be started at 25 mg a day. Most patients need only 75 mg a day to achieve a blood level of 100 mg/nL. However, the dosage may be raised to 150 mg a day if needed. Amoxapine use should be started at 150 mg a day and raised to 400 mg a day. Protriptyline use should be started at 15 mg a day and raised to 60 mg a day. Maprotiline has been associated with an increased incidence of seizures if the dosage is raised too quickly or is maintained at too high a level. Maprotiline use should be started at 25 mg a day and increased over 4 weeks to 225 mg a day. It should be kept at that level for only 6 weeks and then be reduced to 175 to 200 mg a day.

Persons with chronic pain may be particularly sensitive to adverse effects when TCA use is started. Therefore, treatment should begin with low dosages that are raised in small increments. However, persons with chronic pain may experience relief on long-term low-dosage therapy, such as amitriptyline or nortriptyline at 10 to 75 mg a day.

The TCAs should be avoided in children except as a last resort. Dosing guidelines in children for imipramine include initiation at 1.5 mg/kg a day. The dosage can be titrated to no more than 5 mg/kg a day. In enuresis, the dosage is usually 50 to 100 mg a day taken at bedtime. Clomipramine use can be initiated at 50 mg a day and increased to no more than 3 or 200 mg a day.

When TCA treatment is discontinued, the dosage should first be decreased to three-fourths the maximal dosage for a month. At that time, if no symptoms are present, drug use can be tapered by 25 mg (5 mg for protriptyline) every 4 to 7 days. Slow tapering avoids a cholinergic rebound syndrome consisting of nausea, upset stomach, sweating, headache, neck pain, and vomiting. This syndrome can be treated by reinstituting a small dosage of the drug and tapering more slowly than before. Several case reports note the appearance of rebound mania or hypomania after the abrupt discontinuation of TCA use.

### Plasma Concentrations and Therapeutic Drug Monitoring

Clinical determinations of plasma concentrations should be conducted after 5 to 7 days on the same dosage of medication and 8 to 12 hours after the last dose. Because of variations in absorption and metabolism, there may be a 30- to 50-fold difference in the plasma concentrations in persons given the same dosage of a TCA. Nortriptyline is
unique in its association with a therapeutic window—that is, plasma concentrations below 50 ng/mL or above 150 ng/mL may reduce its efficacy.

Plasma concentrations may be useful in confirming compliance, assessing reasons for drug failures, and documenting effective plasma concentrations for future treatment. Clinicians should always treat the person and not the plasma concentration. Some persons have adequate clinical responses with seemingly subtherapeutic plasma concentrations, and other persons only respond at supratherapeutic plasma concentrations without experiencing adverse effects. The latter situation, however, should alert the clinician to monitor the person’s condition with, for example, serial EKG recordings.

**Overdose Attempts**

Overdose attempts with TCAs are serious and can often be fatal. Prescriptions for these drugs should be nonrefillable and for no longer than 1 week at a time for patients at risk for suicide. Amoxapine may be more likely than the other TCAs to result in death when taken in overdose. The newer antidepressants are safer in overdose.

Symptoms of overdose include agitation, delirium, convulsions, hyperactive deep tendon reflexes, bowel and bladder paralysis, dysregulation of BP and temperature, and mydriasis. The patient then progresses to coma and perhaps respiratory depression. Cardiac arrhythmias may not respond to treatment. Because of the long half-lives of TCAs, the patients are at risk of cardiac arrhythmias for 3 to 4 days after the overdose, so they should be monitored in an intensive care medical setting.

Valproate (Depakene, Depakote), or valproic acid, is approved for the treatment of manic episodes associated with bipolar I disorder and is one of the most widely prescribed mood stabilizers in psychiatry. It has a rapid onset of action and is well tolerated, and numerous studies suggest that it reduces the frequency and intensity of recurrent manic episodes over extended periods of time.

CHEMISTRY

Valproate is a simple-chain branch carboxylic acid. It is called valproic acid because it is rapidly converted to the acid form in the stomach. Multiple formulations of valproic acid are marketed. These include valproic acid (Depakene); divalproex sodium (Depakote), an enteric-coated delayed-release 1:1 mixture of valproic acid and sodium valproate available in tablet and sprinkle formulation (can be opened and spread on food); and sodium valproate injection (Depacon). An extended-release preparation is also available. Each of these is therapeutically equivalent because at physiologic pH, valproic acid dissociates into valproate ion.

PHARMACOLOGIC ACTIONS

Regardless of how it is formulated, valproate is rapidly and completely absorbed 1 to 2 hours after oral administration, with peak concentrations occurring 4 to 5 hours after oral administration. The plasma half-life of valproate is 10 to 16 hours. Valproate is highly protein bound. Protein binding becomes saturated at higher dosages, and
concentrations of therapeutically effective free valproate increase at serum concentrations above 50 to 100 μg/mL. The unbound portion of valproate is considered to be pharmacologically active and can cross the blood–brain barrier. The extended-release preparation produces lower peak concentrations and higher minimum concentrations and can be given once a day. Valproate is metabolized primarily by hepatic glucuronidation and mitochondrial β oxidation.

The biochemical basis of valproate’s therapeutic effects remains poorly understood. Postulated mechanisms include enhancement of GABA activity, modulation of voltage-sensitive sodium channels, and action on extrahypothalamic neuropeptides.

**THERAPEUTIC INDICATIONS**

Valproate is currently approved as monotherapy or adjunctive therapy of complex partial seizures, monotherapy and adjunctive therapy of simple and complex absence seizures, and adjunctive therapy for patients with multiple seizures that include absence seizures. Divalproex has additional indications for prophylaxis of migraine.

**Bipolar I Disorder**

**Acute Mania.** About two-thirds of persons with acute mania respond to valproate. The majority of patients with mania usually respond within 1 to 4 days after achieving valproate serum concentrations above 50 μg/mL. Antimanic response is generally associated with levels greater than 50 μg/mL, in a range of 50 to 150 μg/mL. Using gradual dosing strategies, this serum concentration may be achieved within 1 week of initiation of dosing, but rapid oral loading strategies achieve therapeutic serum concentrations in 1 day and can control manic symptoms within 5 days. The short-term antimanic effects of valproate can be augmented with addition of lithium, carbamazepine (Tegretol), SDAs, or DRAs. Numerous studies have suggested that the irritable manic subtype respond significantly better to divalproex than lithium or placebo. Because of its more favorable profile of cognitive, dermatologic, thyroid, and renal adverse effects, valproate is preferred to lithium for treatment of acute mania in children and elderly persons.

**Acute Bipolar Depression.** Valproate possesses some activity as a short-term treatment of depressive episodes in bipolar I disorder, but this effect is far less pronounced than for treatment of manic episodes. Among depressive symptoms, valproate is more effective for treatment of agitation than dysphoria. In clinical practice, valproate is most often used as add-on therapy to an antidepressant to prevent the development of mania or rapid cycling.

**Prophylaxis.** Studies suggest that valproate is effective in the prophylactic treatment of bipolar I disorder, resulting in fewer, less severe, and shorter manic episodes. In direct comparison, valproate is at least as effective as lithium and is better tolerated than lithium. It may be particularly effective in persons with rapid-cycling and
ultrarapid-cycling bipolar disorders, dysphoric or mixed mania, and mania caused by a general medical condition as well as in persons who have comorbid substance abuse or panic attacks and in persons who have not had complete favorable responses to lithium treatment.

**Schizophrenia and Schizoaffective Disorder**

Valproate may accelerate response to antipsychotic therapy in patients with schizophrenia or schizoaffective disorder. Valproate alone is generally less effective in schizoaffective disorder than in bipolar I disorder. Valproate alone is ineffective for treatment of psychotic symptoms and is typically used in combination with other drugs in patients with these symptoms.

**Other Mental Disorders**

Valproate has been studied for possible efficacy in a broad range of psychiatric disorders. These include alcohol withdrawal and relapse prevention, panic disorder, PTSD, impulse control disorder, borderline personality disorder, and behavioral agitation and dementia. Evidence supporting use in these cases is weak, and any observed therapeutic effects may be related to treatment of comorbid bipolar disorder.

**PRECAUTIONS AND ADVERSE REACTIONS**

Although valproate treatment is generally well tolerated and safe, it carries quite a few black box warnings and other warnings (Table 29.33-1). The two most serious adverse effects of valproate treatment affect the pancreas and liver. Risk factors for potentially fatal hepatotoxicity include young age (younger than 3 years); concurrent use of phenobarbital; and the presence of neurologic disorders, especially inborn errors of metabolism. The rate of fatal hepatotoxicity in persons who have been treated with only valproate is 0.85 per 100,000 persons; no persons older than the age of 10 years have been reported to have died from hepatotoxicity. Therefore, the risk of this adverse reaction in adult psychiatric patients is low. Nevertheless, if symptoms of lethargy, malaise, anorexia, nausea and vomiting, edema, and abdominal pain occur in a person treated with valproate, the clinician must consider the possibility of severe hepatotoxicity. A modest increase in liver function test results does not correlate with the development of serious hepatotoxicity. Rare cases of pancreatitis have been reported; they occur most often in the first 6 months of treatment, and the condition occasionally results in death. Pancreatic function can be assessed and followed with serum amylase concentrations. Other potentially serious consequences of treatment include hyperammonemia-induced encephalopathy and thrombocytopenia. Thrombocytopenia and platelet dysfunction occur most commonly at high dosages and result in the prolongation of bleeding times.

There are multiple concerns regarding the use of valproate during pregnancy. Women who require valproate therapy should therefore inform their physicians if they intend to become pregnant. First trimester use of valproate has been associated with a 3 to 5 percent risk of neural tube defects, as well as an increased risk of other malformations affecting the heart and other organ systems. Multiple reports have also indicated that in utero exposure to valproate may negatively affect cognitive development in children of mothers who take valproate during pregnancy. They have lower IQ scores at age 6 years compared with those exposed to other antiepileptic drugs. Fetal valproate exposure has dose-dependent associations with reduced cognitive abilities across a range of domains at 6 years of age. Valproate exposure may also increase the risk of autistic spectrum disorder.

Valproate is also associated with teratogenicity, most notably neural tube defects (e.g., spina bifida). The risk is about 1 to 4 percent of all women who take valproate during the first trimester of pregnancy. The risk of valproate-induced neural tube defects can be reduced with daily folic acid supplements (1 to 4 mg a day). All women with childbearing potential who take the drug should be given folic acid supplements. Infants breastfed by mothers taking valproate develop serum valproate concentrations 1 to 10
percent of maternal serum concentrations, but no data suggest that this poses a risk to the infant. Valproate is not contraindicated in nursing mothers. Clinicians should not administer the drug to persons with hepatic diseases. Valproate may be especially problematic for adolescent and young women. Cases of polycystic ovarian disease have been reported in women using valproate. Even when the full syndromal criteria for this syndrome are not met, many of these women develop menstrual irregularities, hair loss, and hirsutism. These effects are thought to result from a metabolic syndrome that is driven by insulin resistance and hyperinsulinemia.

The common adverse effects associated with valproate (Table 29.33-2) are those affecting the GI system, such as nausea, vomiting, dyspepsia, and diarrhea. The GI effects are generally most common in the first month of treatment, particularly if the dosage is increased rapidly. Unbuffered valproic acid (Depakene) is more likely to cause GI symptoms than the enteric-coated “sprinkle” or the delayed-release divalproex sodium formulations. Other common adverse effects involve the nervous system, such as sedation, ataxia, dysarthria, and tremor. Valproate-induced tremor may respond well to treatment with β-adrenergic receptor antagonists or gabapentin. Treatment of the other neurologic adverse effects usually requires lowering the valproate dosage.

GI, gastrointestinal.

Weight gain is a common adverse effect, especially in long-term treatment, and can best be treated by strict limitation of caloric intake. Hair loss may occur in 5 to 10 percent of all persons treated, and rare cases of complete loss of body hair have been reported. Some clinicians have recommended treatment of valproate-associated hair loss...
with vitamin supplements that contain zinc and selenium. About 5 to 40 percent of persons experience a persistent but clinically insignificant elevation in liver transaminases up to three times the upper limit of normal, which is usually asymptomatic and resolves after discontinuation of the drug. High dosages of valproate (above 1,000 mg a day) may rarely produce mild to moderate hyponatremia, most likely because of some degree of the syndrome of secretion of inappropriate antidiuretic hormone, which is reversible upon lowering of the dosage. Overdoses of valproate can lead to coma and death.

**DRUG INTERACTIONS**

Valproate is commonly prescribed as part of a regimen involving other psychotropic agents. The only consistent drug interaction with lithium, if both drugs are maintained in their respective therapeutic ranges, is the exacerbation of drug-induced tremors, which can usually be treated with β-receptor antagonists. The combination of valproate and DRAs may result in increased sedation, as can be seen when valproate is added to any CNS depressant (e.g., alcohol), and an increased severity of extrapyramidal symptoms, which usually responds to treatment with antiparkinsonian drugs. Valproate can usually be safely combined with carbamazepine or SDAs. Perhaps the most worrisome interaction of valproate and a psychotropic drug involves lamotrigine. Since the approval of lamotrigine for the treatment of bipolar disorder, the likelihood that patients will be treated with both agents has increased. Valproate more than doubles lamotrigine concentrations, increasing the risk of a serious rash (Stevens-Johnson syndrome, and toxic epidermal necrolysis).

The plasma concentrations of carbamazepine, diazepam (Valium), amitriptyline (Elavil), nortriptyline (Pamelor), and phenobarbital (Luminal) may also be increased when these drugs are coadministered with valproate, and the plasma concentrations of phenytoin (Dilantin) and desipramine (Norpramin) may be decreased when they are combined with valproate. The plasma concentrations of valproate may be decreased when the drug is coadministered with carbamazepine and may be increased when coadministered with guanfacine (Tenex), amitriptyline, or fluoxetine (Prozac). Valproate can be displaced from plasma proteins by carbamazepine, diazepam, and aspirin. Persons who are treated with anticoagulants (e.g., aspirin and warfarin [Coumadin]) should also be monitored when valproate use is initiated to assess the development of any undesired augmentation of the anticoagulation effects. Interactions of valproate with other drugs are listed in Table 29.33-3.

---

**Table 29.33-3**

**Interactions of Valproate with Other Drugs**
LABORATORY INTERFERENCES

Valproate may cause laboratory increase of serum-free fatty acids. Valproate metabolites may produce a false-positive test result for urinary ketones as well as falsely abnormal thyroid function test results.

DOSAGE AND CLINICAL GUIDELINES

When starting valproate therapy, a baseline hepatic panel, CBC and platelet counts, and pregnancy testing should be ordered. Additional testing should include amylase and coagulation studies if baseline pancreatic disease or coagulopathy is suspected. In addition to baseline laboratory tests, hepatic transaminase concentrations should be obtained 1 month after initiation of therapy and every 6 to 24 months thereafter. However, because even frequent monitoring may not predict serious organ toxicity, it is more prudent to reinforce the need for prompt evaluation of any illnesses when reviewing the instructions with patients. Asymptomatic elevation of transaminase concentrations up to three times the upper limit of normal are common and do not require any change in dosage. Table 29.33-4 lists the recommended laboratory tests for valproate treatment.

CNS, central nervous system.
Valproate is available in a number of formulations (Table 29.33-5). For treatment of acute mania, an oral loading strategy of initiation with 20 to 30 mg/kg a day can be used to accelerate control of symptoms. This is usually well tolerated but can cause excessive sedation and tremor in elderly persons. Agitated behavior can be rapidly stabilized with IV infusion of valproate. If acute mania is absent, it is best to initiate drug treatment gradually to minimize the common adverse effects of nausea, vomiting, and sedation. The dose on the first day should be 250 mg administered with a meal. The dosage can be raised up to 250 mg orally three times daily over the course of 3 to 6 days. The plasma concentrations can be assessed in the morning before the first daily dose is administered. Therapeutic plasma concentrations for the control of seizures range between 50 and 150 μg/mL, but concentrations up to 200 μg/mL are usually well tolerated. It is reasonable to use the same range for the treatment of mental disorders; most of the controlled studies have used 50 to 125 μg/mL. Most persons attain therapeutic plasma concentrations on a dosage between 1,200 and 1,500 mg a day in divided doses. After a person's symptoms are well controlled, the full daily dose can be taken all at once before sleep.

Thousands of herbal and dietary supplements are being marketed today. Some are purported to have psychoactive properties. A number have even shown promise in the treatment of certain psychiatric symptoms. Although certain compounds may be beneficial, in many cases the quantity and quality of data have been insufficient to make definitive conclusions. Nevertheless, some patients prefer to use these substances in place of, or in conjunction with, standard pharmaceutical treatments. If electing to use herbal drugs or nutritional supplements, bear in mind that their use may come at the expense of proven interventions and that adverse effects are possible. Though more research is needed, information published to date is still of clinical interest in diagnosing and treating patients who may be taking dietary supplements.

Additionally, herbal and nonherbal supplements may augment or antagonize the actions of prescription and nonprescription drugs. Thus, it is important for clinicians to remain informed on the latest research involving these substances. Because of the paucity of clinical trials, the clinician must be extraordinarily alert to the possibility of adverse effects as a result of drug–drug interactions, especially if psychotropic agents are prescribed, because many phytomedicinals have ingredients that produce physiological changes in the body.

NUTRITIONAL SUPPLEMENTS

In the United States, the term nutritional supplement is used interchangeably with the term dietary supplement. The Dietary Supplement Health and Education Act (DHSEA) of 1994 defined nutritional supplements as items taken by mouth that contain a “dietary ingredient” meant to supplement the diet. These ingredients may include vitamins, minerals, herbs, botanicals, amino acids, and substances such as enzymes, tissues, glandulars, and metabolites. By law such products must be labeled as supplements and may not be marketed as conventional food.

The DSHEA places dietary supplements in a special category, and therefore the regulations governing them are more lax than those for prescription and over-the-counter drugs. Unlike pharmaceutical drugs, nutritional supplements do not need the approval of the U.S. Food and Drug Administration (FDA), and the FDA does not evaluate their effectiveness. Because dietary supplements are not regulated by the FDA, the contents and quality on store shelves vary dramatically. Contamination, mislabeling, and misidentification of herbs and supplements are important problems. Table 29.34-1 provides a list of dietary supplements used in psychiatry.

In recent years the FDA has introduced a new category of nutritional supplement called medical foods. According to the FDA, medical food, as defined in the Orphan Drug Act, is “a food which is formulated to be consumed or administered enterally under the supervision of a physician and which is intended for the specific dietary management of a disease or condition for which distinctive nutritional requirements, based on recognized scientific principles, are established by medical evaluation.”

A clear distinction can be made between the regulatory classifications of medical foods and dietary supplements. Medical foods must be shown, by medical evaluation, to meet the distinctive nutritional needs of a specific population of patients with a specific disease being targeted. Dietary supplements, on the other hand, are intended for normal, healthy adults and may not require proof of efficacy of the finished product. Medical foods are distinguished from the broader category of foods for special dietary use and from foods that make health claims by the requirement that medical foods are to be used under medical supervision.

Medical foods do not have to undergo premarket approval by the FDA. But medical food firms must comply with other requirements, such as good manufacturing practices and registration of food facilities. Medical foods do have some additional regulations that dietary supplements do not because medical foods are intended to treat illnesses. For example, a compliance program requires annual inspections of all medical food

(Tables by Mercedes Rábade, M.D.)
In summary, to be considered a medical food a product must, at a minimum, meet the following criteria: (1) The product must be a food for oral or tube feeding; (2) the product must be labeled for the dietary management of a specific medical disorder, disease, or condition for which there is distinctive nutritional requirements; and (3) the product must be intended to be used under medical supervision. The most common medical foods with psychoactive claims are listed in Table 29.34-2.

### PHYTOMEDICINALS

The term *phytomedicinals* (from the Greek *phyto*, meaning “plant”) refers to herb and plant preparations that are used or have been used for centuries for the treatment of a variety of medical conditions. Phytomedicinals are categorized as dietary supplements, not drug products, and are therefore exempt from the regulations that govern prescription and over-the-counter medications. Manufacturers of phytomedicinals are not required to provide the FDA with safety information before marketing a product or give the FDA postmarketing safety reports. Thousands of herbal drugs are being marketed today; the most common with psychoactive properties are listed in Table 29.34-3. Ingredients, to the extent they have been identified, are listed, as indications, adverse events, dosages, and comments, particularly on interactions with commonly prescribed drugs used in psychiatry. For example, St. John’s wort (*wort* is an old English word meaning “root or herb”), which is used to treat depression, decreases the effectiveness of certain psychotropic drugs such as amitriptyline (Elavil), alprazolam...
(Xanax), paroxetine (Paxil), and sertraline (Zoloft), among others. Kava kava, which is used to treat anxiety states, has been associated with liver toxicity.

Drug Interactions and Adverse Effects:
- **Antipsychotics**: Increase the risk of hypotension and orthostatic hypotension.
- **MAOIs**: Increase the risk of serotonin syndrome.
- **Corticosteroids**: Weaken the immune system and increase the risk of infection.
- **Diuretics**: Increase the risk of renal impairment.

**Notes:**
- Always consult a healthcare professional before starting any new medication.
- Regular monitoring of blood pressure and heart rate is necessary.
- Monitor for signs of infection and increased bruising.
- Avoid driving or operating machinery until side effects are understood.
- Store medications in a cool, dry place, away from children and pets.
Adverse Effects

Adverse effects are possible, and toxic interactions with other drugs may occur with all phytomedicinals, dietary supplements, and medicinal foods. Adulteration is possible, especially with phytomedicinals. There are few or no consistent standard preparations available for most herbs. Medical foods are not tested by the FDA; however, strict voluntary compliance is required. Safety profiles and knowledge of adverse effects of most of these substances have not been studied rigorously, however. Because of the paucity of clinical trials, all of these agents should be avoided during pregnancy; some herbs may act as abortifacients, for example. Because most of these substances or their metabolites are secreted in breast milk, they are contraindicated during lactation.

Clinicians should always attempt to obtain a history of herbal use or the use of medical foods or nutritional supplements during the psychiatric evaluation.

It is important to be nonjudgmental in dealing with patients who use these substances. Many do so for various reasons: (1) as part of their cultural tradition, (2) because they mistrust physicians or are dissatisfied with conventional medicine, or (3) because they experience relief of symptoms with the particular substance. Because patients will be more cooperative with traditional psychiatric treatments if they are allowed to continue using their preparations, psychiatrists should try to keep an open mind and not attribute all effects to suggestion. If psychotropic agents are prescribed, the clinician must be extraordinarily alert to the possibility of adverse effects as a result of drug–drug interactions because many of these compounds have ingredients that produce actual physiological changes in the body.
Weight management is an important element of psychotropic drug treatment because obesity is common among persons with mental disorders. Thus, medical conditions such as hypertension, diabetes mellitus, and hyperlipidemia need to be taken into account when selecting medications. With few exceptions, most psychotropic drugs used to manage mood disorders, anxiety disorders, and psychosis are associated with significant risk of weight gain as a side effect. Many patients may refuse or discontinue treatment if weight gain occurs, even if the drug is effective in treating their symptoms. For this and other reasons, it is important for clinicians to be well informed about treatment strategies for mitigating drug-induced weight gain and obesity in general.

The standard recommendation for weight loss regimens consists of attempting to manage body weight through consistent dietary modifications and regular physical activity. This may be difficult for patients struggling with psychiatric symptoms because their ability to be disciplined in this effort can be compromised by their mental disorder. Also, the physiologic effects of some psychotropic drugs on regulation of satiety and on body metabolism are difficult, if not impossible, to overcome through diet and exercise alone. For these reasons, it may be necessary to use prescription medications to facilitate weight loss.

In this section, drugs used to manage obesity are categorized in two ways: (1) drugs

---

**References**

approved by the U.S. Food and Drug Administration (FDA) as diet pills; and (2) drugs with primary indications other than weight loss but produce weight loss as a side effect.

**DRUGS WITH U.S. FOOD AND DRUG ADMINISTRATION APPROVAL FOR WEIGHT LOSS**

All of the drugs approved by the FDA as weight loss agents are specifically indicated as an adjunct to a reduced calorie diet and increased physical activity for chronic weight management in adult patients with an initial body mass index (BMI) of 30 kg/m$^2$ or greater (obese) or 27 kg/m$^2$ or greater (overweight) in the presence of at least one weight-related comorbidity such as hypertension, type 2 diabetes mellitus, or dyslipidemia.

**Phentermine**

Phentermine hydrochloride (Adipex-P) is a sympathomimetic amine with pharmacological activity similar to the amphetamines. It is indicated as a short-term adjunct in a regimen of weight reduction, but in fact, many patients use the drug for extended periods. As with all sympathomimetics, contraindications include advanced arteriosclerosis, cardiovascular disease, moderate to severe hypertension, hyperthyroidism, known hypersensitivity or idiosyncrasy to the sympathomimetic amines, agitated states, and glaucoma.

The drug should be prescribed with caution to patients with a history of drug abuse. Hypertensive crises may result if phentermine is used during or within 14 days following the administration of monoamine oxidase inhibitors (MAOIs). Insulin requirements in diabetes mellitus may be altered in association with the use of phentermine hydrochloride and the concomitant dietary regimen. Phentermine hydrochloride may decrease the hypotensive effect of guanethidine. Phentermine is pregnancy Category X and thus contraindicated during pregnancy. Studies have not been performed with phentermine hydrochloride to determine the potential for carcinogenesis, mutagenesis, or impairment of fertility.

Phentermine should be taken on an empty stomach, once daily, prior to breakfast. Tablets may be broken or cut in half but should not be crushed. To avoid disrupting normal sleep patterns, it should be dosed early in the day. If taking more than one dose a day, the last dose should be taken approximately 4 to 6 hours prior to going to bed. The recommended dose of phentermine may be different for different patients. Adults under age 60 taking phentermine using 15- to 37.5-mg capsules should take them once per day before breakfast or 1 to 2 hours after breakfast. Those using 15- to 37.5-mg tablets should take them once per day before breakfast or 1 to 2 hours after breakfast. Instead of taking it once a day, some patients may take 15 to 37.5 mg in divided doses a half hour before meals. An oral resin formulation is available in 15- and 30-mg capsules, which should be taken once per day before breakfast.
Phentermine/Topiramate Extended Release (Qsymia)

This drug is a combination of phentermine and topiramate (Topamax). The phentermine/topiramate combination was approved by the FDA in 2012 as an extended-release formulation. Both active agents in this formulation are associated with weight loss through separate mechanisms.

Adverse events associated with the use of this drug may include, but are not limited to, paresthesia, dizziness, dysgeusia, insomnia, constipation, dry mouth, kidney stones, metabolic acidosis, and secondary angle closure glaucoma. Use of this drug is associated with a fivefold increased risk of infants with cleft palate and is classified as pregnancy Category X. As a result, it can only be prescribed by clinicians who have been certified in the use of this drug.

It is available as a tablet and should be administered once daily in the morning with or without food. Avoid dosing with the drug in the evening due to the possibility of insomnia. The recommended dose is as follows: Start treatment with 3.75 mg/23 mg (phentermine/topiramate extended release) daily for 14 days; after 14 days increase the recommended dose to 7.5 mg/46 mg once daily. Evaluate weight loss after 12 weeks of treatment 7.5 mg/46 mg. If at least 3 percent of baseline body weight has not been lost on 7.5 mg/46 mg, discontinue the drug or escalate the dose. To escalate the dose, increase to 11.25 mg/69 mg daily for 14 days; followed by dosing 15 mg/92 mg daily. Evaluate weight loss following dose escalation to 15 mg/92 mg after an additional 12 weeks of treatment. If at least 5 percent of baseline body weight has not been lost on 15 mg/92 mg, discontinue the medication gradually.

Phendimetrazine (Bontril PDM Adipost, Phendiet, Statobex)

Phendimetrazine is a sympathomimetic amine that is closely related to the amphetamines. It is classified by the Drug Enforcement Agency (DEA) as a Schedule III controlled substance.

Overall prescribing of this agent is limited. The most commonly used formulation is the 105-mg extended-release capsule, which approximates the action of three 35-mg immediate-release doses taken at 4-hour intervals. The average half-life of elimination when studied under controlled conditions is about 3.7 hours for both the extended-release and immediate-release forms. The absorption half-life of the drug from the immediate-release 35-mg phendimetrazine tablets is appreciably more rapid than the absorption rate of the drug from the extended-release formulation. The major route of elimination is via the kidneys, where most of the drug and metabolites are excreted.

Phendimetrazine contraindications are similar to those of phentermine. They include history of cardiovascular disease (e.g., coronary artery disease, stroke, arrhythmias, congestive heart failure, uncontrolled hypertension, pulmonary hypertension); use during or within 14 days following the administration of MAOIs; hyperthyroidism; glaucoma; agitated states; history of drug abuse; pregnancy; nursing; use in combination with other anorectic agents or central nervous system (CNS) stimulants;
and known hypersensitivity or idiosyncratic reactions to sympathomimetics. Given the lack of systematic research, phendimetrazine should not be used in combination with over-the-counter preparations and herbal products that claim to promote weight loss.

Phendimetrazine tartrate is considered pregnancy Category X and is contraindicated during pregnancy because weight loss offers no potential benefit to a pregnant woman and may result in fetal harm. Studies with phendimetrazine tartrate sustained release have not been performed to evaluate carcinogenic potential, mutagenic potential, or effects on fertility.

Interactions may occur with MAOIs, alcohol, insulin, and oral hypoglycemic agents. Phendimetrazine may decrease the hypotensive effect of adrenergic neuron blocking drugs. The effectiveness and the safety of phendimetrazine in pediatric patients have not been established. It is not recommended in patients less than 17 years of age.

Adverse reactions reported with phendimetrazine include sweating, flushing, tremor, insomnia, agitation, dizziness, headache, psychosis, and blurred vision. Elevated blood pressure, palpitations, and tachycardia are common. Gastrointestinal side effects include dry mouth, nausea, stomach pain, diarrhea, and constipation. Genitourinary side effects include frequency, dysuria, and changes in libido.

Phendimetrazine tartrate is related chemically and pharmacologically to the amphetamines. Amphetamines and related stimulant drugs have been extensively abused, and the possibility of abuse of phendimetrazine should be kept in mind when evaluating the desirability of including a drug as part of a weight reduction program.

Acute overdose with phendimetrazine may manifest itself by restlessness, confusion, belligerence, hallucinations, and panic states. Fatigue and depression usually follow the central stimulation. Cardiovascular effects include tachycardia, arrhythmias, hypertension or hypotension, and circulatory collapse. Gastrointestinal symptoms include nausea, vomiting, diarrhea, and abdominal cramps. Poisoning may result in convulsions, coma, and death. The management of acute overdose is largely symptomatic. It includes lavage and sedation with a barbiturate. If hypertension is marked, the use of a nitrate or rapid-acting \( \alpha \)-receptor–blocking agent should be considered.

**Diethylpropion (Tenuate)**

Diethylpropion preceded its analog, the antidepressant drug bupropion (Wellbutrin). Diethylpropion comes in two formulations: a 25-mg tablet and a 75-mg extended-release tablet (Tenuate Dospan). It is usually taken three times a day, 1 hour before meals (regular tablets), or once a day in midmorning (extended-release tablets). The extended-release tablets should be swallowed whole, never crushed, chewed, or cut. The maximum daily dose is 75 mg.

Side effects include dry mouth, unpleasant taste, restlessness, anxiety, dizziness, depression, tremors, upset stomach, vomiting, and increased urination. Side effects that warrant medical attention include tachycardia, palpitations, blurred vision, skin rash, itching, difficulty breathing, chest pain, fainting, swelling of the ankles or feet, fever,
sore throat, chills, and painful urination. Diethylpropion is classified pregnancy Category B and has a low abuse potential. It is listed as a Schedule IV drug by the DEA.

**Orlistat (Xenical, Alli)**

Orlistat interferes with the absorption of dietary fats, causing reduced caloric intake. It works by inhibiting gastric and pancreatic lipases, the enzymes that break down triglycerides in the intestine. When lipase activity is blocked, triglycerides from the diet are not hydrolyzed into absorbable free fatty acids and are excreted undigested instead. Only trace amounts of orlistat are absorbed systemically; it is almost entirely eliminated through the feces.

The effectiveness of orlistat in promoting weight loss is definite, though modest. When used as part of weight loss program, between 30 and 50 percent of patients can expect a 5 percent or greater decrease in body mass. About 20 percent achieve at least a 10 percent decrease in body mass. After orlistat is stopped, up to a third of people gain the weight they lose.

Among the benefits of orlistat treatment are a decrease in blood pressure and a reduced risk of developing type 2 diabetes.

The most common subjective side effects of orlistat are gastrointestinal related, and include steatorrhea, flatulence, fecal incontinence, and frequent or urgent bowel movements. To minimize these effects, foods with high fat content should be avoided; a low-fat, reduced calorie diet is advisable. Ironically, orlistat can be used with high-fat content diets to treat constipation that results from treatment with some psychotropic drugs, such as the tricyclic antidepressants. Side effects are most severe when beginning therapy and may decrease in frequency with time. Hepatic and renal injuries are potentially serious side effects of orlistat use. In 2010, new safety information about rare cases of severe liver injury was added to the product label of orlistat. The rate of acute kidney injury is more common among orlistat users than nonusers. It should be used with caution in patients with impaired liver function and renal function, as well as those with an obstructed bile duct and pancreatic disease. Orlistat is contraindicated in malabsorption syndromes, hypersensitivity to orlistat, reduced gallbladder function, and in pregnancy and breast-feeding. Orlistat is rated pregnancy Category X.

Absorption of fat-soluble vitamins and other fat-soluble nutrients is inhibited by the use of orlistat. Multivitamin supplements that contain vitamins A, D, E, K, as well as β-carotene should be taken once a day, preferably at bedtime.

Orlistat can reduce plasma levels of the immunosuppressant cyclosporine (Sandimmune), so the two drugs should therefore not be administered concomitantly. Orlistat can also impair absorption of the antiarrhythmic amiodarone (Nexterone).

At the standard prescription dose of 120 mg three times daily before meals, orlistat prevents approximately 30 percent of dietary fat from being absorbed. Higher doses have not been shown to produce more pronounced effects.

An over-the-counter formulation of orlistat (Alli) is available as 60-mg capsules—half the dosage of prescription orlistat.
Lorcaserin (Belviq)

This drug is awaiting approval by the FDA because it appears to have hallucinogenic potential. The exact mechanism of action of lorcaserin is not known, but it most likely decreases food consumption and promotes satiety through selective activation of 5-HT$_{2C}$ receptors on neurons in the hypothalamus.

The effect of multiple oral doses of lorcaserin 15 mg and 40 mg once daily on QTc interval has been evaluated in healthy subjects. The largest placebo adjusted, baseline-corrected QTc based on individual correction method (QTcI) was below 10 milliseconds, the threshold for regulatory concern.

Lorcaserin is absorbed from the gastrointestinal tract, with peak plasma concentration occurring 1.5 to 2 hours after oral dosing. The absolute bioavailability of lorcaserin has not been determined. Lorcaserin has a plasma half-life of approximately 11 hours; steady state is reached within 3 days after twice daily dosing, and accumulation is estimated to be approximately 70 percent. Lorcaserin can be administered with or without food. Lorcaserin hydrochloride is moderately bound (approximately 70 percent) to human plasma proteins.

It is extensively metabolized in the liver by multiple enzymatic pathways, and the metabolites are excreted in the urine. Lorcaserin and its metabolites are not cleared by hemodialysis. It is not recommended for patients with severe renal impairment (creatinine clearance less than 30 mL per minute) or patients with end-stage renal disease.

The half-life of lorcaserin is prolonged by 59 percent to 19 hours in patients with moderate hepatic impairment. Lorcaserin exposure (area under the curve) is approximately 22 and 30 percent higher in patients with mild and moderate hepatic impairment, respectively. Dose adjustment is not required for patients with mild to moderate hepatic impairment.

No dosage adjustment based on gender is necessary because it did not meaningfully affect the pharmacokinetics of lorcaserin. No dosage adjustment is required based on age alone.

Lorcaserin significantly inhibits CYP2D6-mediated metabolism.

DRUGS WITHOUT U.S. FOOD AND DRUG ADMINISTRATION APPROVAL FOR WEIGHT LOSS

Topiramate

Topiramate and zonisamide (Zonegran) are discussed more fully in Section 29.6, but are mentioned here because both agents can have a substantial effect on weight loss.

Topiramate is approved as an antiepileptic drug and for prevention in adults of migraine headaches. The degree of weight loss associated with topiramate may be comparable to the weight loss that other FDA-approved antiobesity drugs induce. Small studies and extensive anecdotal reports indicate that topiramate can help to offset
weight gain associated with selective serotonin reuptake inhibitors (SSRIs) and second-generation antipsychotic drugs. Its impact on body weight may be due to its effects on both appetite suppression and satiety enhancement. These may be the result of a combination of pharmacological effects including augmenting γ-aminobutyric acid (GABA) activity, modulation of voltage-gated ion channels, inhibition of excitatory glutamate receptors, or inhibition of carbonic anhydrase.

The duration and dosage of treatment affect the weight loss benefits of topiramate. Weight loss is higher when the drug is prescribed at doses of 100 to 200 mg per day for more than a month compared with less than a month. In a large study it was shown that compared to those who took placebo, topiramate-treated patients were seven times more likely to lose more than 10 percent of their body weight. In clinical practice, many patients experience weight loss at a starting dose of 25 mg per day.

The most common side effects of topiramate are paresthesias, typically around the mouth, impaired taste (taste perversion), and psychomotor disturbances, including slowed cognition and reduced physical movements. Concentration and memory impairment, often characterized by word finding and name recall problems, is often reported. Some patients may experience emotional lability and mood changes. Medical side effects include increased risk of kidney stones and acute-angle closure glaucoma. Patients should report any change in visual acuity. Those with a history of kidney stones should be instructed to drink adequate amounts of fluid.

Topiramate is available as 25-, 50- 100-, and 200-mg tablets and as 15-, 25-, and 50-mg capsules.

Zonisamide

Zonisamide is a sulfonamide-related drug, similar in many ways to topiramate. Its exact mechanism of action is not known. Like topiramate, it can cause cognitive problems, but the incidence is lower than that with topiramate.

Zonisamide has been assigned to pregnancy Category C. Animal studies have revealed evidence of teratogenicity. Fetal abnormalities or embryo-fetal deaths have been reported in animal tests at zonisamide dosage and maternal plasma levels similar to, or lower than, human therapeutic levels. Therefore, use of this drug in human pregnancy may expose the fetus to significant risk.

The most common side effects include drowsiness, loss of appetite, dizziness, headache, nausea, and agitation or irritability. Zonisamide has also been associated with hypohidrosis. There is a 2 to 4 percent risk of kidney stones. Other drugs known to provoke stones, such as topiramate or acetazolamide (Diamox), should not be combined with zonisamide. Serious, but rare, adverse drug reactions include Stevens-Johnson syndrome, toxic epidermal necrolysis, and metabolic acidosis.

Typical dosing for weight loss has not been established. Generally, zonisamide is started at 100 mg at night for 2 weeks, and increased by 100 mg daily every 2 weeks to a target dose of 200 to 600 mg per day in one or two daily doses.
Metformin (Glucophage)

Metformin is a medication for type 2 diabetes mellitus. Its actions include reduction of hepatic glucose production, reduced intestinal glucose absorption, increased insulin sensitivity, and improved peripheral glucose uptake and regulation. It does not increase insulin secretion.

When used as an adjunct to second-generation antipsychotics, it has consistently been shown to reduce body weight and waist circumference. Metformin probably has the best evidence of therapeutic benefit for the treatment of antipsychotic drug–induced metabolic syndrome. In several studies, metformin has been shown to attenuate or reverse some of the weight gain induced by antipsychotics. The degree of effect on body weight compares favorably with the effect of other treatment options that are approved for weight reduction. The weight loss effect of adjunctive metformin appears to be stronger in drug-naive patients treated with second-generation antipsychotic medications. This effect is most evident for those being treated with clozapine (Clozaril) and olanzapine (Zyprexa). Based on the existing evidence, if weight gain occurs after second-generation antipsychotic initiation, despite lifestyle intervention, metformin should be considered.

Common side effects include nausea, vomiting, abdominal pain, and loss of appetite. Gastrointestinal side effects can be mitigated by dividing the dose, taking the drug after meals, or using delayed-release formulations.

One serious treatment risk is that of lactic acidosis. This side effect is more common in those with reduced renal function. Although very rare (approximately 9 in 100,000 persons per year), it has a 50 percent mortality rate. Alcohol use along with metformin can increase the risk of acidosis. Renal function monitoring and alcohol avoidance are important.

The weight loss effects of metformin are also evident in chronically ill patients with schizophrenia. Long-term use of metformin appears to be safe and effective.

There is no clearly established dose range for metformin when used as an adjunct for weight loss. In most reports, the usual dose ranged from 500 to 2,000 mg per day. The maximum dose used in treating diabetes is 850 mg three times daily. Patients usually start with a low dose to see how the drug affects them.

Metformin is available in 500-, 850-, and 1,000-mg tablets, all now generic. Metformin SR (slow release) or XR (extended release) is available in 500- and 750-mg strengths. These formulations are intended to reduce gastrointestinal side effects and to increase patient compliance by reducing pill burden.

Amphetamine

Amphetamine is a psychostimulant approved for the treatment of attention-deficit/hyperactivity disorder and narcolepsy. It has the effect of reducing appetite and has been used off label for that purpose for many years. Some of the drugs discussed above have amphetamine-like properties, which account for their effectiveness.
Amphetamines and other psychostimulants are discussed fully in Section 29.30.

REFERENCES

30.1 Electroconvulsive Therapy

Convulsive therapies for major psychiatric illnesses predate the modern therapeutic era, with the use of camphor reported as early as the 16th century and the existence of several accounts of camphor convulsive therapies from the late 1700s to the mid-1800s. Unaware of the history of camphor convulsive therapy, the Hungarian neuropsychiatrist Ladislas von Meduna made the observation that the brains of epileptics had greater than normal numbers of glial cells, whereas those of schizophrenics had fewer, and he hypothesized that there might be a biological antagonism between convulsions and schizophrenia. Following animal experimentation, camphor was (again) selected as the appropriate agent to use for the therapeutic induction of seizures. In 1934, the first catatonic psychotic patient was successfully treated using intramuscular injections of camphor in oil to produce therapeutic seizures. Lucio Bini and Ugo Cerletti were interested in the use of electricity to induce seizures, and, after a series of animal experiments and observation of the use of electricity commercially, they were able to safely apply current across the heads of animals for this purpose. In 1938, the first electroconvulsive treatment (ECT) course was administered to a delusional and incoherent patient, who improved with one treatment and remitted after 11 treatments. Electrical induction of convulsive therapy could be made more reliable and shorter acting than chemically induced convulsive therapies, and, by the early 1940s, it had replaced them. In 1940, the first use of ECT occurred in the United States.

In an effort to reduce the retrograde memory problems that persisted for some patients after the initial recovery period post-ECT, explorations of nondominant electrode placement and alternative, more efficient waveforms were undertaken in subsequent decades. The practice of ECT also benefited from the introduction of controlled trials methodology, which demonstrated its safety and efficacy, and from refinements made in diagnostic systems and the process of informed consent. In the 1980s and 1990s efforts to ensure uniformly high standards of practice were under way with the publication of recommendations for treatment delivery, education, and training by professional organizations in the United States, England, Scandinavia, and Canada, among others.

With the widespread use of pharmacological agents as first-line treatments for major psychiatric disorders, ECT is now more commonly used for patients with resistance to those treatments, except in the case of life-threatening illness due to inanition, severe suicidal symptoms, or catatonia. Although the failure of subconvulsive stimulation to
induce the remission of psychiatric illness and the effectiveness of chemical convulsive therapy suggested that the seizure was necessary and sufficient for therapeutic benefit with ECT, it is now known that there is a dose–response relationship with right unilateral ECT and that bilateral ECT is likely to be ineffective with ultrabrief pulse widths. Work continues to explore the underlying mechanisms and biological characteristics of effective ECT treatments, with interest in having the treatment focus on appropriate neural networks with a more efficient stimulus as a method of reducing cognitive side effects. With the growing understanding that depression is a chronic disease for many patients, more emphasis has been placed on continuation and maintenance treatments following an acute course of ECT. Utilization of ECT has diminished since the middle of the 20th century; but because ECT remains the most effective treatment for major depression and a rapidly effective treatment for life-threatening psychiatric conditions, ECT, unlike its contemporaneous somatic therapies, such as insulin coma, remains in the active treatment portfolio of modern therapeutics. Its use has shifted from public to private institutions, and it is estimated that approximately 100,000 patients have received ECT annually over the past few decades in the United States (Table 30.1-1).

| Table 30.1-1 | Milestones in the History of Convulsive Therapy |
The Nobel Laureate Paul Greengard has suggested that the term electrocortical therapy might be used to replace the current term electroconvulsive therapy. Greengard has acknowledged that if the mechanism of action of ECT, as yet unknown, turns out to be subcortical, then the term might have limited use. Until that time, however, the authors of this text think Greengard’s suggestion deserves consideration. It would help diminish the fear associated with the word convulsion and help destigmatize a very effective treatment method.

**ELECTROPHYSIOLOGY IN ELECTROCONVULSIVE THERAPY**

Neurons maintain a resting potential across the plasma membrane and may propagate an action potential, which is a transient reversal of the membrane potential. Normal brain activity is desynchronized; that is, neurons fire action potentials asynchronously. A convulsion, or seizure, occurs when a large percentage of neurons fire in unison. Such rhythmical changes in the extracellular potential entrain neighboring neurons, propagate the seizure activity across the cortex and into deeper structures, and eventually engulf the entire brain in high-voltage synchronous neuronal firing. Cellular mechanisms work to contain the seizure activity and to maintain cellular homeostasis,
and the seizure eventually ends. In epilepsy, any of possibly several hundred genetic defects can alter the balance in favor of unrestrained activity. In ECT, seizures are triggered in normal neurons by application through the scalp of pulses of current, under conditions that are carefully controlled to create a seizure of a particular duration over the entire brain.

The qualities of the electricity used in ECT can be described by Ohm’s law: $E = IR$, or $I = E/R$, in which $E$ is voltage, $I$ is current, and $R$ is resistance. The intensity or dose of electricity in ECT is measured in terms of charge (milliampere-seconds or millicoulombs) or energy (watt-seconds or joules). Resistance is synonymous with impedance and, in the case of ECT, both the electrode’s contact with the body and the nature of the bodily tissues are the major determinants of resistance. The skull has a high impedance; the brain has a low impedance. Because scalp tissues are much better conductors of electricity than bone, only about 20 percent of the applied charge actually enters the skull to excite neurons. The ECT machines that are now widely used can be adjusted to administer the electricity under conditions of constant current, voltage, or energy.

MECHANISM OF ACTION

The induction of a bilateral generalized seizure is necessary for both the beneficial and the adverse effects of ECT. Although a seizure superficially seems as though it is an all-or-none event, some data indicate that not all generalized seizures involve all the neurons in deep brain structures (e.g., the basal ganglia and the thalamus); recruitment of these deep neurons may be necessary for full therapeutic benefit. After the generalized seizure, the electroencephalogram (EEG) shows about 60 to 90 seconds of postictal suppression. This period is followed by the appearance of high-voltage delta and theta waves and a return of the EEG to preseizure appearance in about 30 minutes. During the course of a series of ECT treatments, the interictal EEG is generally slower and of greater amplitude than usual, but the EEG returns to pretreatment appearance 1 month to 1 year after the end of the course of treatment.

One research approach to the mechanism of action for ECT has been to study the neurophysiological effects of treatment. Positron emission tomography (PET) studies of both cerebral blood flow and glucose use have shown that, during seizures, cerebral blood flow, use of glucose and oxygen, and permeability of the blood–brain barrier increase. After the seizure, blood flow and glucose metabolism are decreased, perhaps most markedly in the frontal lobes. Some research indicates that the degree of decrease in cerebral metabolism is correlated with therapeutic response.

Seizure foci in idiopathic epilepsy are hypometabolic during interictal periods; ECT itself acts as an anticonvulsant because its administration is associated with an increase in the seizure threshold as treatment progresses. Recent data suggest that for 1 to 2 months following a session of ECT, EEGs record a large increase in slow-wave activity located over the prefrontal cortex in patients who responded well to the ECT. High-intensity, bilateral stimulation produced the best response; low-intensity, unilateral stimulation, the weakest. These data are of unclear significance, however, because the
specific EEG correlate disappeared 2 months after ECT, whereas the clinical benefit persisted.

ECT affects the cellular mechanisms of memory and mood regulation and raises the seizure threshold. The latter effect may be blocked by the opiate antagonist naloxone (Narcan).

Neurochemical research into the mechanisms of action of ECT has focused on changes in neurotransmitter receptors and, recently, changes in second-messenger systems. Virtually every neurotransmitter system is affected by ECT, but a series of ECT sessions results in downregulation of postsynaptic β-adrenergic receptors, the same receptor change observed with virtually all antidepressant treatments. The effects of ECT on serotonergic neurons remain controversial. Various research studies have reported an increase in postsynaptic serotonin receptors, no change in serotonin receptors, and a change in the presynaptic regulation of serotonin release. ECT has also been reported to effect changes in the muscarinic, cholinergic, and dopaminergic neuronal systems. In second-messenger systems, ECT has been reported to affect the coupling of G-proteins to receptors, the activity of adenylyl cyclase and phospholipase C, and the regulation of calcium entry into neurons.

Recently, there has been increased interest in structural changes in the brain associated with psychiatric syndromes and response to treatment. This has been particularly so for microscopic changes associated with electroconvulsive stimulation, as well as antidepressant and other medications. In animals, mostly rodents, synaptic plasticity in hippocampus, including mossy fiber sprouting, alterations in cytoskeletal structure, increased connectivity in perforant pathways, promotion of neurogenesis, and suppression of apoptosis have been observed. Many of these structural events are also observed, although to a lesser extent, with antidepressant medications such as fluoxetine (Prozac). These reports have also galvanized controversy over various aspects of the technical validity of the observations. It is unknown whether such changes occur clinically and, if they do, what significance to efficacy and cognitive side effects might be discovered.

**INDICATIONS**

**Major Depressive Disorder**

The most common indication for ECT is major depressive disorder, for which ECT is the fastest and most effective available therapy. ECT should be considered for use in patients who have failed medication trials, have not tolerated medications, have severe or psychotic symptoms, are acutely suicidal or homicidal, or have marked symptoms of agitation or stupor. Controlled studies have shown that up to 70 percent of patients who fail to respond to antidepressant medications may respond positively to ECT. Table 30.1-2 presents the indications for the use of ECT.

<table>

<tr>
<th>Indications for the Use of Electroconvulsive Therapy</th>
</tr>
</thead>
</table>
ECT is effective for depression in both major depressive disorder and bipolar I disorder. Delusional or psychotic depression has long been considered particularly responsive to ECT; but recent studies have indicated that major depressive episodes with psychotic features are no more responsive to ECT than nonpsychotic depressive disorders. Nevertheless, because major depressive episodes with psychotic features respond poorly to antidepressant pharmacotherapy alone, ECT should be considered much more often as the first-line treatment for patients with the disorder. Major depressive disorder with melancholic features (e.g., markedly severe symptoms, psychomotor retardation, early morning awakening, diurnal variation, decreased appetite and weight, and agitation) is considered likely to respond to ECT. ECT is particularly indicated for persons who are severely depressed, who have psychotic symptoms, who show suicidal intent, or who refuse to eat. Depressed patients less likely to respond to ECT include those with somatization disorder. Elderly patients tend to respond to ECT more slowly than do young patients. ECT is a treatment for major depressive episode and does not provide prophylaxis unless it is administered on a long-term maintenance basis.

**Manic Episodes**

ECT is at least equal to lithium (Eskalith) in the treatment of acute manic episodes. The pharmacological treatment of manic episodes, however, is so effective in the short term and for prophylaxis that the use of ECT to treat manic episodes is generally limited to situations with specific contraindications to all available pharmacological approaches. The relative rapidity of the ECT response indicates its usefulness for patients whose manic behavior has produced dangerous levels of exhaustion. ECT should not be used for
a patient who is receiving lithium, because lithium can lower the seizure threshold and cause a prolonged seizure.

**Schizophrenia**

Although an effective treatment for the symptoms of acute schizophrenia, ECT is not for those of chronic schizophrenia. Patients with schizophrenia who have marked positive symptoms, catatonia, or affective symptoms are considered most likely to respond to ECT. In such patients, the efficacy of ECT is about equal to that of antipsychotics, but improvement may occur faster.

**Other Indications**

Small studies have found ECT effective in the treatment of catatonia, a symptom associated with mood disorders, schizophrenia, and medical and neurological disorders. ECT is also reportedly useful to treat episodic psychoses, atypical psychoses, obsessive-compulsive disorder, and delirium and such medical conditions as neuroleptic malignant syndrome, hypopituitarism, intractable seizure disorders, and the on–off phenomenon of Parkinson’s disease. ECT may also be the treatment of choice for depressed suicidal pregnant women who require treatment and cannot take medication; for geriatric and medically ill patients who cannot take antidepressant drugs safely; and perhaps even for severely depressed and suicidal children and adolescents who may be less likely to respond to antidepressant drugs than are adults. ECT is not effective in somatization disorder (unless accompanied by depression), personality disorders, and anxiety disorders.

**CLINICAL GUIDELINES**

Patients and their families are often apprehensive about ECT; therefore, clinicians must explain both beneficial and adverse effects and alternative treatment approaches. The informed-consent process should be documented in the patients’ medical records and should include a discussion of the disorder, its natural course, and the option of receiving no treatment. Printed literature and videotapes about ECT may be useful in attempting to obtain a truly informed consent. The use of involuntary ECT is rare today and should be reserved for patients who urgently need treatment and who have a legally appointed guardian who has agreed to its use. Clinicians must know local, state, and federal laws about the use of ECT.

**Pretreatment Evaluation**

Pretreatment evaluation should include standard physical, neurological, and preanesthesia examinations and a complete medical history. Laboratory evaluations should include blood and urine chemistries, a chest X-ray, and an electrocardiogram (ECG). A dental examination to assess the state of patients’ dentition is advisable for elderly patients and patients who have had inadequate dental care. An X-ray of the
spine is needed if other evidence of a spinal disorder is seen. Computed tomography (CT) or magnetic resonance imaging (MRI) should be performed if a clinician suspects the presence of a seizure disorder or a space-occupying lesion. Practitioners of ECT no longer consider even a space-occupying lesion to be an absolute contraindication to ECT, but with such patients the procedure should be performed only by experts.

**Concomitant Medications.** Patients’ ongoing medications should be assessed for possible interactions with the induction of a seizure, for effects (both positive and negative) on the seizure threshold, and for drug interactions with the medications used during ECT. The use of tricyclic and tetracyclic drugs, monoamine oxidase inhibitors, and antipsychotics is generally considered acceptable. Benzodiazepines used for anxiety should be withdrawn because of their anticonvulsant activity; lithium should be withdrawn because it can result in increased postictal delirium and can prolong seizure activity; clozapine (Clozaril) and bupropion (Wellbutrin) should be withdrawn because they are associated with the development of late-appearing seizures. Lidocaine (Xylocaine) should not be administered during ECT because it markedly increases the seizure threshold; theophylline (Theo-Dur) is contraindicated because it increases the duration of seizures. Reserpine (Serpasil) is also contraindicated because it is associated with further compromise of the respiratory and cardiovascular systems during ECT.

**Premedications, Anesthetics, and Muscle Relaxants**

Patients should not be given anything orally for 6 hours before treatment. Just before the procedure, the patient’s mouth should be checked for dentures and other foreign objects, and an intravenous (IV) line should be established. A bite block is inserted in the mouth just before the treatment is administered to protect the patient’s teeth and tongue during the seizure. Except for the brief interval of electrical stimulation, 100 percent oxygen is administered at a rate of 5 L a minute during the procedure until spontaneous respiration returns. Emergency equipment for establishing an airway should be immediately available in case it is needed.

**Muscarinic Anticholinergic Drugs.** Muscarinic anticholinergic drugs are administered before ECT to minimize oral and respiratory secretions and to block bradycardias and asystoles, unless the resting heart rate is above 90 beats a minute. Some ECT centers have stopped the routine use of anticholinergics as premedications, although their use is still indicated for patients taking β-adrenergic receptor antagonists and those with ventricular ectopic beats. The most commonly used drug is atropine, which can be administered 0.3 to 0.6 mg intramuscularly (IM) or subcutaneously (SC) 30 to 60 minutes before the anesthetic or 0.4 to 1.0 mg IV 2 or 3 minutes before the anesthetic. An option is to use glycopyrrolate (Robinul) (0.2 to 0.4 mg IM, IV, or SC), which is less likely to cross the blood–brain barrier and less likely to cause cognitive dysfunction and nausea, although it is thought to have less cardiovascular protective activity than does atropine.
Anesthesia.   Administration of ECT requires general anesthesia and oxygenation. The depth of anesthesia should be as light as possible, not only to minimize adverse effects but also to avoid elevating the seizure threshold associated with many anesthetics. Methohexital (Brevital) (0.75 to 1.0 mg/kg IV bolus) is the most commonly used anesthetic because of its shorter duration of action and lower association with postictal arrhythmias than thiopental (Pentothal) (usual dose 2 to 3 mg/kg IV), although this difference in cardiac effects is not universally accepted. Four other anesthetic alternatives are etomidate (Amidate), ketamine (Ketalar), alfentanil (Alfenta), and propofol (Diprivan). Etomidate (0.15 to 0.3 mg/kg IV) is sometimes used because it does not increase the seizure threshold; this effect is particularly useful for elderly patients because the seizure threshold increases with age. Ketamine (6 to 10 mg/kg IM) is sometimes used because it does not increase the seizure threshold, although its use is limited by the frequent association of psychotic symptoms with emergence from anesthesia with this drug. Alfentanil (2 to 9 mg/kg IV) is sometimes coadministered with barbiturates to allow the use of low doses of the barbiturate anesthetics and, thus, reduce the seizure threshold less than usual, although its use can be associated with an increased incidence of nausea. Propofol (0.5 to 3.5 mg/kg IV) is less useful because of its strong anticonvulsant properties.

Muscle Relaxants.   After the onset of the anesthetic effect, usually within a minute, a muscle relaxant is administered to minimize the risk of bone fractures and other injuries resulting from motor activity during the seizure. The goal is to produce profound relaxation of the muscles, not necessarily to paralyze them, unless the patient has a history of osteoporosis or spinal injury or has a pacemaker and, therefore, is at risk for injury related to motor activity during the seizure. Succinylcholine (Anectine), an ultrafast-acting depolarizing blocking agent, has gained virtually universal acceptance for the purpose. Succinylcholine is usually administered in a dose of 0.5 to 1 mg/kg as an IV bolus or drip. Because succinylcholine is a depolarizing agent, its action is marked by the presence of muscle fasciculations, which move in a rostrocaudal progression. The disappearance of these movements in the feet or the absence of muscle contractions after peripheral nerve stimulation indicates maximal muscle relaxation. In some patients, tubocurarine (3 mg IV) is administered to prevent myoclonus and increases in potassium and muscle enzymes; these reactions can be a problem in patients with musculoskeletal or cardiac disease. To monitor the duration of the convulsion, a blood pressure cuff may be inflated at the ankle to a pressure in excess of the systolic pressure before infusion of the muscle relaxant to allow observation of relatively innocuous seizure activity in the foot muscles.

If a patient has a known history of pseudocholinesterase deficiency, atracurium (Tracrium) (0.5 to 1 mg/kg IV) or curare can be used instead of succinylcholine. In such a patient, the metabolism of succinylcholine is disrupted, and prolonged apnea may necessitate emergency airway management. In general, however, because of the short half-life of succinylcholine, the duration of apnea after its administration is generally shorter than the delay in regaining consciousness caused by the anesthetic and the
Electrode Placement. Historically, most practitioners have used bifrontotemporal electrode placement because of its reliability in producing efficacy and its ease of use. This electrode placement is also associated with more short-term and long-term adverse cognitive effects and is more likely to produce delirium, which may require interrupting a course of ECT and perhaps even terminating it before optimal therapeutic effects have been obtained. Hence, when bifrontotemporal ECT is used, attention should be paid to restricting the dose to a moderately suprathreshold level to attenuate adverse cognitive effects as much as possible. It should be emphasized that the combination of ultrabrief pulse and bifrontotemporal electrode placement has not been demonstrated to be effective. Treatment with bilateral electrode placements, particularly a bifrontal configuration, is more likely to manifest EEG seizure without motor seizure, and EEG monitoring can be particularly useful in detecting its occurrence.

Newer electrode placements include bifrontal configuration and asymmetrical placements. There are limitations to these strategies, imposed by the fact that the high impedance of the skull and scalp causes spreading of the electrical stimulus and restricts possibilities for localization of the stimulus. Bifrontal electrode placement, with positioning far enough laterally to minimize interference with impedance relations, has been investigated, and there have been several demonstrations that bifrontal electrode placements are equally effective to bifrontotemporal and adequately dosed right unilateral electrode configurations. Evidence of advantages in sparing of cognitive effects is quite preliminary, and adequately powered investigations with more extensive and sensitive cognitive batteries are needed. Seizure threshold is likely to be relatively higher with bifrontal ECT.

The relatively better cognitive side effect profile of right unilateral ECT should encourage wider use now that the efficacy of this electrode placement can be ensured with adequate dosing strategies. In contrast to bilateral ECT, a dose closer to 500 percent above the seizure threshold is more likely to ensure efficacy. ECT devices in the United States are restricted to an output in the range of 504 to 576 mCi. Approximately 90 percent of patients have seizure thresholds that can accommodate optimal dosing with brief-pulse right unilateral ECT, and the combination of right unilateral electrode placement with ultrabrief pulse width extends the range of US devices so that most patients can be treated within these constraints. Individuals with an exceptionally high seizure threshold may require bilateral electrode placements to remain within the device restrictions. Maximizing interelectrode distance by using the d'Elia placement may also be optimal. Many other right unilateral placements have been described, but there is little work to support their use (Fig. 30.1-1).
Electrode placements. Position 1 represents the frontotemporal position, used for both electrodes, one on each side of the head, in conducting bilateral electroconvulsive therapy (ECT). For right unilateral ECT, one electrode is in the right frontotemporal position, and the other is just to the right of the vertex at position 2. (Courtesy of American Psychiatric Association, with permission.)

There has been some concern that left-handed patients may require different electrode placement than right-handed patients, especially if unilateral placement is desired. Even when handedness is lateralized to the left, the anatomic localization of language function in 70 percent of left-handed individuals is the same as in those who are right-handed. Furthermore, there is evidence for independent lateralization of affect, with the right hemisphere involved in sustaining depressed mood regardless of handedness. Because of limited indications that affective function and efficacy of ECT are associated with handedness, handedness is not generally used to guide the choice of electrode placement.

**Electrical Stimulus**

The electrical stimulus must be sufficiently strong to reach the seizure threshold (the level of intensity needed to produce a seizure). The electrical stimulus is given in cycles, and each cycle contains a positive and a negative wave. Old machines use a sine wave; however, this type of machine is now considered obsolete because of the inefficiency of that wave shape. When a sine wave is delivered, the electrical stimulus in the sine wave before the seizure threshold is reached and after the seizure is activated is unnecessary and excessive. Modern ECT machines use a brief pulse waveform that administers the
electrical stimulus usually in 1 to 2 milliseconds at a rate of 30 to 100 pulses a second. Machines that use an ultrabrief pulse (0.5 milliseconds) are not as effective as brief pulse machines.

Establishing a patient’s seizure threshold is not straightforward. A 40 times variability in seizure thresholds occurs among patients. In addition, during the course of ECT treatment, a patient’s seizure threshold may increase 25 to 200 percent. The seizure threshold is also higher in men than in women and higher in older than in younger adults. A common technique is to initiate treatment at an electrical stimulus that is thought to be below the seizure threshold for a particular patient and then to increase this intensity by 100 percent for unilateral placement and by 50 percent for bilateral placement until the seizure threshold is reached. A debate in the literature concerns whether a minimally suprathreshold dose, a moderately suprathreshold dose (one and a half times the threshold), or a high suprathreshold dose (three times the threshold) is preferable. The debate about stimulus intensity resembles the debate about electrode placement. Essentially, the data support the conclusion that doses of three times the threshold are the most rapidly effective and that minimal suprathreshold doses are associated with the fewest and least severe cognitive adverse effects.

**Induced Seizures**

A brief muscular contraction, usually strongest in a patient’s jaw and facial muscles, is seen concurrently with the flow of stimulus current, regardless of whether a seizure occurs. The first behavioral sign of the seizure is often a plantar extension, which lasts 10 to 20 seconds and marks the tonic phase. This phase is followed by rhythmic (i.e., clonic) contractions that decrease in frequency and finally disappear. The tonic phase is marked by high-frequency, sharp EEG activity on which a higher frequency muscle artifact may be superimposed. During the clonic phase, bursts of polyspike activity occur simultaneously with the muscular contractions but usually persist for at least a few seconds after the clonic movements stop.

**Monitoring Seizures.** A physician must have an objective measure that a bilateral generalized seizure has occurred after the stimulation. The physician should be able to observe either some evidence of tonic-clonic movements or electrophysiological evidence of seizure activity from the EEG or electromyogram (EMG). Seizures with unilateral ECT are asymmetrical, with higher ictal EEG amplitudes over the stimulated hemisphere than over the nonstimulated hemisphere. Occasionally, unilateral seizures are induced; for this reason, at least a single pair of EEG electrodes should be placed over the contralateral hemisphere when using unilateral ECT. For a seizure to be effective in the course of ECT, it should last at least 25 seconds.

**Failure to Induce Seizures.** If a particular stimulus fails to cause a seizure of sufficient duration, up to four attempts at seizure induction can be tried during a course of treatment. The onset of seizure activity is sometimes delayed as long as 20 to 40
seconds after the stimulus administration. If a stimulus fails to result in a seizure, the
contact between the electrodes and the skin should be checked, and the intensity of the
stimulus should be increased by 25 to 100 percent. The clinician can also change the
anesthetic agent to minimize increases in the seizure threshold caused by the anesthetic.
Additional procedures to lower the seizure threshold include hyperventilation and
administration of 500 to 2,000 mg IV of caffeine sodium benzoate 5 to 10 minutes
before the stimulus.

**Prolonged and Tardive Seizures.** Prolonged seizures (seizures lasting more than
180 seconds) and status epilepticus can be terminated either with additional doses of the
barbiturate anesthetic agent or with IV diazepam (Valium) (5 to 10 mg). Management
of such complications should be accompanied by intubation, because the oral airway is
insufficient to maintain adequate ventilation over an extended apneic period. Tardive
seizures—that is, additional seizures appearing some time after the ECT treatment—may
develop in patients with preexisting seizure disorders. Rarely, ECT precipitates the
development of an epileptic disorder in patients. Such situations should be managed
clinically as if they were pure epileptic disorders.

**Number and Spacing of Treatments**
ECT treatments are usually administered two to three times a week; twice-weekly
treatments are associated with less memory impairment than thrice-weekly treatments.
In general, the course of treatment of major depressive disorder can take 6 to 12
treatments (although up to 20 sessions are possible); the treatment of manic episodes
can take 8 to 20 treatments; the treatment of schizophrenia can take more than 15
treatments; and the treatment of catatonia and delirium can take as few as 1 to 4
treatments. Treatment should continue until the patient achieves what is considered the
maximal therapeutic response. Further treatment does not yield any therapeutic benefit,
but increases the severity and duration of the adverse effects. The point of maximal
improvement is usually thought to occur when a patient fails to continue to improve
after two consecutive treatments. If a patient is not improving after 6 to 10 sessions,
bilateral placement and high-density treatment (three times the seizure threshold)
should be attempted before ECT is abandoned.

**Multiple-Monitored Electroconvulsive Therapy.** Multiple-monitored ECT
(MMECT) involves giving multiple ECT stimuli during a single session, most commonly
two bilateral stimuli within 2 minutes. This approach may be warranted in severely ill
patients and in those at especially high risk from the anesthetic procedures. MMECT is
associated with the most frequent occurrences of serious cognitive adverse effects.

**Maintenance Treatment**
A short-term course of ECT induces a remission in symptoms but does not, of itself,
prevent a relapse. Post-ECT maintenance treatment should always be considered.
Maintenance therapy is generally pharmacological, but maintenance ECT treatments (weekly, biweekly, or monthly) have been reported to be effective relapse prevention treatments, although data from large studies are lacking. Indications for maintenance ECT treatments can include rapid relapse after initial ECT, severe symptoms, psychotic symptoms, and the inability to tolerate medications. If ECT was used because a patient was unresponsive to a specific medication, then, following ECT, the patient should be given a trial of a different medication.

**Failure of Electroconvulsive Therapy Trial**

Patients who fail to improve after a trial of ECT should again be treated with the pharmacological agents that failed in the past. Although the data are primarily anecdotal, many reports indicate that patients who had previously failed to improve while taking an antidepressant drug do improve while taking the same drug after receiving a course of ECT treatments, even if the ECT seemed to be a therapeutic failure. Nonetheless, with the increased availability of drugs that act at diverse receptor sites, it is less often necessary to return to a drug that has failed than it was formerly.

**ADVERSE EFFECTS**

**Contraindications**

ECT has no absolute contraindications, only situations in which a patient is at increased risk and has an increased need for close monitoring. Pregnancy is not a contraindication for ECT, and fetal monitoring is generally considered unnecessary unless the pregnancy is high risk or complicated. Patients with space-occupying central nervous system lesions are at increased risk for edema and brain herniation after ECT. If the lesion is small, however, pretreatment with dexamethasone (Decadron) is given, and hypertension is controlled during the seizure and the risk of serious complications minimized for these patients. Patients who have increased intracerebral pressure or are at risk for cerebral bleeding (e.g., those with cerebrovascular diseases and aneurysms) are at risk during ECT because of the increased cerebral blood flow during the seizure. This risk can be lessened, although not eliminated, by control of the patient’s blood pressure during the treatment. Patients with recent myocardial infarctions are another high-risk group, although the risk is greatly diminished 2 weeks after the myocardial infarction and is even further reduced 3 months after the infarction. Patients with hypertension should be stabilized on their antihypertensive medications before ECT is administered. Propranolol (Inderal) and sublingual nitroglycerin can also be used to protect such patients during treatment.

**Mortality**

The mortality rate with ECT is about 0.002 percent per treatment and 0.01 percent for each patient. These numbers compare favorably with the risks associated with general
anesthesia and childbirth. ECT death is usually from cardiovascular complications and is most likely to occur in patients whose cardiac status is already compromised.

**Central Nervous System Effects**

Common adverse effects associated with ECT are headache, confusion, and delirium shortly after the seizure while the patient is coming out of anesthesia. Marked confusion may occur in up to 10 percent of patients within 30 minutes of the seizure and can be treated with barbiturates and benzodiazepines. Delirium is usually most pronounced after the first few treatments and in patients who receive bilateral ECT or who have coexisting neurological disorders. The delirium characteristically clears within days or a few weeks at the longest.

**Memory.** The greatest concern about ECT is the association between ECT and memory loss. About 75 percent of all patients given ECT say that the memory impairment is the worst adverse effect. Although memory impairment during a course of treatment is almost the rule, follow-up data indicate that almost all patients are back to their cognitive baselines after 6 months. Some patients, however, complain of persistent memory difficulties. For example, a patient may not remember the events leading up to the hospitalization and ECT, and such autobiographical memories may never be recalled. The degree of cognitive impairment during treatment and the time it takes to return to baseline are related, in part, to the amount of electrical stimulation used during treatment. Memory impairment is most often reported by patients who have experienced little improvement with ECT. Despite the memory impairment, which usually resolves, no evidence indicates brain damage caused by ECT. This subject has been the focus of several brain-imaging studies, using a variety of modalities; virtually all concluded that permanent brain damage is not an adverse effect of ECT. Neurologists and epileptologists generally agree that seizures that last less than 30 minutes do not cause permanent neuronal damage.

**Other Adverse Effects of Electroconvulsive Therapy**

Fractures often accompanied treatments in the early days of ECT. With routine use of muscle relaxants, fractures of long bones or vertebrae should not occur. Some patients, however, may break teeth or experience back pain because of contractions during the procedure. Muscle soreness can occur in some individuals, but it often results from the effects of muscle depolarization by succinylcholine and is most likely to be particularly troublesome after the first session in a series. This soreness can be treated with mild analgesics, including nonsteroidal anti-inflammatory drugs (NSAIDs). A significant minority of patients experience nausea, vomiting, and headaches following an ECT treatment. Nausea and vomiting can be prevented by treatment with antiemetics at the time of ECT (e.g., metoclopramide [Reglan], 10 mg IV, or prochlorperazine [Compazine], 10 mg IV; ondansetron [Zofran] is an acceptable alternative if adverse effects preclude use of dopamine receptor antagonists).
ECT can be associated with headaches, although this effect is usually readily manageable. Headaches often respond to NSAIDs given in the ECT recovery period. In patients with severe headaches, pretreatment with ketorolac (Toradol) (30 to 60 mg IV), an NSAID approved for brief parenteral use, can be helpful. Acetaminophen (Tylenol), tramadol (Ultram), propoxyphene (Darvon), and more potent analgesia provided by opioids can be used individually or in various combinations (e.g., pretreatment with ketorolac and postseizure management with acetaminophen-propoxyphene) to manage more intractable headache. ECT can induce migrainous headache and related symptoms; sumatriptan (Imitrex) (6 mg SC or 25 mg orally) may be a useful addition to the agents described above. Ergot compounds can exacerbate cardiovascular changes observed during ECT and probably should not be a component of ECT pretreatment.

INVESTIGATIONS IN ELECTRICAL BRAIN STIMULATION TREATMENT

There is interest in continued refinements of ECT techniques. Common themes in these approaches are focusing the treatment spatially to optimize dosing in brain areas associated with putative neural networks involved in depression and other psychopathologies that are indications for ECT, diminishing dosing in areas associated with adverse cognitive effects, and improving the efficiency of a noninvasive electrical stimulus in direction and amplitude, even to a subconvulsive level. This research is parallel to investigations in magnetic stimulation (e.g., repetitive transcranial magnetic stimulation) and to the renaissance of invasive electrical techniques (e.g., vagal nerve stimulation and deep brain stimulation).

REFERENCES

30.2 Other Brain Stimulation Methods

Brain stimulation in psychiatric practice and research uses electrical currents or magnetic fields to alter neuronal firing. There is a growing list of tools capable of eliciting such neuromodulation, each with a different spectrum of action. These tools either apply electrical or magnetic fields transcranially or involve the surgical implantation of electrodes to deliver electrical currents to a cranial nerve or to the brain directly. The transcranial techniques include cranial electrical stimulation (CES), electroconvulsive therapy (ECT), transcranial direct current stimulation (tDCS, also called direct current polarization), transcranial magnetic stimulation (TMS), and magnetic seizure therapy (MST). The surgical techniques include cortical brain stimulation (CBS), deep brain stimulation (DBS), and vagus nerve stimulation (VNS).

In 1985, nearly 50 years after the first use of ECT, Anthony Barker and colleagues published on the first use of pulsed magnetic fields to stimulate the brain with a procedure called transcranial magnetic stimulation. TMS was initially used in neurology for studies of nerve conduction, but it quickly caught the attention of psychiatrists eager to explore other, less invasive alternatives to ECT. This nonconvulsive stimulation method through TMS is under active study, with some promising results in the treatment of various psychiatric disorders, including depression, anxiety, and schizophrenia, as described by Sarah H. Lisanby, Leann H. Kinnunen, and colleagues in 2002. In the past decade, a convulsive treatment derived from the application of more powerful magnetic stimulation has been under investigation in nonhuman primates and in human studies in both the United States and Europe. The first MST procedure was performed in an animal in 1998 and in a human in 2000. MST is under development as a more focal means of inducing seizures in an attempt to retain the thus-far-unparalleled efficacy of ECT with fewer cognitive side effects.

Two more recent additions to brain stimulation methods, DBS and VNS, were introduced about a decade following the first trials of TMS. Both were first approved by the U.S. Food and Drug Administration (FDA) in 1997 in the realm of treating sequelae of neurological syndromes. DBS was initially approved for the treatment of essential tremor and Parkinson's tremor, whereas VNS was approved for the treatment of epilepsy. Five years later, in 2002, indications for DBS
were expanded to include treatment of all symptoms of Parkinson’s disease, including tremor, slowness, and stiffness, as well as involuntary movements induced by medications. TMS, DBS, and VNS originated in the field of neurology. Psychiatrists quickly saw the potential for those tools in the treatment of psychiatric conditions, however, and as a result of clinical trials in depression, VNS subsequently received FDA approval for the adjunctive long-term treatment of chronic or recurrent depression in adults. In addition, human studies are under way to validate the efficacy of DBS in the treatment of depression and obsessive-compulsive disorder.

THERAPEUTIC NEUROMODULATION: TREATING PSYCHIATRIC DISORDERS THROUGH BRAIN STIMULATION

Mechanism of Action

Electrical Stimulation—Common Pathway. The brain stimulation modalities just reviewed generate either electrical or magnetic pulses. However, both of these share a common final pathway—they affect the neurons electrically. That electrical effect may either be through the direct application of electricity or through the indirect induction of electricity via magnetic stimulation. The direct forms of electrical stimulation are exemplified in either transcranial delivery, as with ECT, CES, and tDCS, or intracerebral delivery, as in the case of DBS or direct cortical stimulation (epidural or subdural). The indirect forms of electrical stimulation include TMS and MST, which induce electrical fields in the brain through the application of alternating magnetic fields. Of note, both the epidural and intracerebral modalities are more focal than the transcranial application of electricity because electrodes are placed directly in the neuronal tissue, bypassing the impedance of the scalp and skull. The relatively more contemporary magnetic stimulation methods (TMS and MST) also bypass the impedance of the scalp and skull and are thus likewise more focal. However, magnetic stimulation is in fact an example of an indirect method of electrical brain stimulation, in that the changing magnetic fields from these devices induce electricity in the brain, the latter acting as a conductor, according to the principle first described by Michael Faraday in a law that bears his name and later incorporated into James Clerk Maxwell’s equations, which unify all of electromagnetism. The magnetic modalities achieve their enhanced focality noninvasively, in contrast to the intracerebral and epidural methods, and are thus at the center of intensive research in that they offer the promise of an unparalleled degree of spatial specificity without the need for surgery.

All but one of the brain stimulation modalities described here act by stimulating neurons. The one exception is tDCS, which does not stimulate but rather polarizes. In this sense, the “S” of tDCS is a misnomer. It is more accurate to conceptualize tDCS as exerting a polarizing effect that may alter the likelihood of neuronal firing.

The action of the subconvulsive modalities of stimulation relies on the effects of the repeated stimulation of the targeted neural circuitry. However, in the case of the convulsive modalities (ECT and MST), the action depends on the seizure induced by the stimulation and the effects of repeated seizure induction on brain processes. This is not to say that the form of stimulation that triggers the seizure has no effect on outcome. Indeed, it is well replicated that electrode placement and electrical stimulus parameters have a profound effect on the efficacy and side effects of ECT. Whether the same will be true for MST is under active investigation.
Acute versus Prolonged Effects. Brain stimulation can have immediate or lasting effects. A single electrical pulse delivered at sufficient intensity can induce depolarization, trigger an action potential, release neurotransmitters at the synapse, and result in transsynaptic propagation with subsequent activation of a functional circuit. For example, brain stimulation applied to the hand area of the primary motor cortex may activate the corticospinal tract and induce a muscle twitch in the contralateral hand. Such stimulation can result acutely in the induction of either a positive effect, as in the case of a muscle twitch or visualization of phosphenes, or a disruptive effect, as in the case of visual masking.

Repetitive pulses delivered at fixed frequencies can exert even more powerful effects. Epstein and colleagues described in 1999 how repetitive TMS (rTMS) applied to the language-dominant hemisphere induced an arrest of speech. After termination of the stimulation, speech returned to normal.

Some more invasive brain stimulation modalities, such as DBS or VNS, are programmed to operate chronically, thus extending the acute action for as long as the stimulation is turned on. In the case of DBS, the pulses are typically given continuously at a high frequency, whereas in the case of VNS the pulses are given in trains lasting up to 30 seconds and typically repeated every 5 minutes. The less invasive modalities, such as rTMS, tDCS, CES, and even ECT, presumably require the induction of some form of neuroplasticity for their effect to become lasting.

**TRANSCRANIAL MAGNETIC STIMULATION**

**Definition**

TMS is the application of a rapidly changing magnetic field to the superficial layers of the cerebral cortex, which locally induces small electric currents, also referred to as *eddy* currents. This induction was originally discovered by Faraday through his experiments in 1831 and later quantified in Maxwell’s equations of electromagnetism. Thus, TMS may be referred to as electrical stimulation without an electrode, in that it uses magnetic fields to indirectly induce electrical pulses. TMS devices deliver strong magnetic pulses via a coil that is held on the scalp. Because magnetic fields are unaffected by the electrical impedance of the scalp and skull, this method of stimulation enables the focal stimulation of smaller areas of the brain than is possible with other noninvasive devices that use either alternating (ECT, CES) or direct (tDCS) electrical current for primary stimulation. TMS is an example of noninvasive stimulation of focal regions of the brain and, as such, can be used for research or therapeutically without the need for anesthesia.

**Mechanisms of Action**

At sufficient intensity, electrical currents will stimulate neuronal depolarization, which can result in an action potential. For example, when the TMS coil is positioned over the hand area of the cerebral cortex’s motor strip, the changing magnetic field generated by
the repetitive pulses induces local currents immediately below the site of stimulation that cause the neurons in area M1 to fire. In turn, this action potential propagates through the polysynaptic corticospinal tract and results in a twitch in the contralateral hand muscle. In summary, TMS uses magnetic fields to indirectly induce focal electrical currents in the brain, thereby triggering the firing of functional neuronal circuits that can lead to observable behavioral effects. This effect can be easily demonstrated by single TMS pulses that can be used to map the homunculus simply by moving the TMS coil across the cortical representation of neighboring muscle groups and simultaneously to study the excitability of the corticospinal system.

Single TMS pulses can exert other effects when moved to different cortical areas. When positioned over the primary visual cortex (V1), scotomas, or “blind spots,” are often elicited. This illustrates that TMS can transiently disrupt functions. Activation of motor neurons resulting in a muscle twitch and disruption of visual perception with a single-pulse TMS represent examples of the acute effects of TMS-induced neuronal depolarization, as shown in Table 30.2-1. The effects of single TMS pulses are believed to be immediate and short lived. The muscle twitch as induced by TMS to area M1 is nearly instantaneous, with the hand movement occurring approximately 20 milliseconds after the TMS pulse is applied. The visual masking likewise operates on a similar time scale measured in milliseconds. TMS can, however, exert longer-lasting effects when the pulses are repeated at regular intervals in a process of rTMS or when they are paired with other forms of stimulation in which TMS pulses are coupled with electrical stimulation of a peripheral nerve (as in paired associative stimulation [PAS]) or when TMS is paired with audiovisual stimuli, as in the example of classical conditioning of the brain response to TMS. The mechanisms underlying these lasting effects of TMS have been described by various researchers and are thought to be related to neuroplasticity and alterations in synaptic efficacy.

Treatment of psychiatric disorders with rTMS has been informed by attempts to focally alter pathological cortical excitability, believed to be linked to a specific illness. Reduced activity in the left dorsolateral prefrontal cortex has been implicated in several studies as a physiological correlate of affective disorders. To correct this, numerous studies have applied high frequencies of rTMS, which have been reported to increase excitability, to the left dorsolateral prefrontal cortex (DLPFC) in an attempt to normalize activity in this region. In a related approach, some investigators who implicated abnormal interhemispheric balance in activation between the right and left DLPFC applied low-frequency rTMS, which has been reported to be inhibitory, to the right DLPFC in an attempt to normalize this balance.

Side Effects, Interactions with Medications, and Other Risks
Administration of TMS is a noninvasive, relatively benign procedure when applied by a knowledgeable professional to a subject who has been properly evaluated. However, it is not entirely without risk. The most serious known risk of TMS is an unintended seizure. There are several factors that may contribute to seizure risk. Primarily, these include the form of TMS, with single-pulse stimulation less likely to result in a seizure than rTMS, and, in an equally important manner, the dose, which is the combination of treatment parameters including frequency, power, train duration, and intertrain interval. In addition, subject factors can be important, such as the presence of a neurological disorder (epilepsy or a focal brain lesion) or use of seizure-lowering medications.

Single-pulse TMS is generally considered to be of minimal risk when administered to appropriately screened adults without seizure risk factors. On the other hand, rTMS can induce seizures in individuals without predisposing conditions when given at sufficiently high doses.

**Patient Selection**

Patients who have failed a trial of one or more antidepressant medications or have untoward side effects to medications may be good candidates for TMS. However, given the lower effect size of TMS, for urgent or severely refractory cases, ECT would remain the ultimate gold standard treatment.

**Future Directions and Controllable Pulse Shape TMS**

TMS and other forms of magnetic stimulation hold a tremendous promise in psychiatric treatment due to their focality and noninvasiveness. However, much research is needed to replicate preliminary findings, improve optimal dosing, establish the patient characteristics that predict response, and examine the influence of concomitant medications on TMS effect. Posttreatment relapse prevention is one of many areas that have to be properly explored. Other vigorously pursued directions are attempts to develop stimulation coils that will allow deeper brain penetration and work on pulse shapes that may be more physiologically optimal for human stimulation.

**TRANSCRANIAL DIRECT CURRENT STIMULATION**

**Definition**

Transcranial direct current stimulation is a noninvasive form of treatment that uses very weak (1 to 3 mA) direct electrical current applied to the scalp. Because direct current (DC) polarizes rather than stimulates with discrete pulses, its action does not appear directly to result in action potential firing in cortical neurons. It is also this DC form of electrical stimulation that distinguishes it from devices that use alternating currents (AC) as found in CES, ECT, VNS, and DBS, which produce discrete pulse stimulation. In addition, because tDCS works via polarization and does not affect action potential firing
in cortical neurons, the term *transcranial direct current polarization* is favored by some modern investigators, and both terms appear interchangeably in the literature today. The small device is very portable and usually operated by readily available DC batteries.

**Side Effects**

There are no known serious adverse effects of tDCS. It is well tolerated, with reported common side effects in the literature listing mostly minimal tingling at the site of stimulation, with a few reported cases of skin irritation.

**Mechanism of Action**

Direct current polarizes current, and tDCS is believed to act via the alteration of neuronal membrane polarization, but little is known about the actual mechanism of action of tDCS. Polarization may affect the firing and conductance of neurons by either lowering or raising the threshold of activation. Because tDCS involves the application of low currents to the scalp via cathodal and anodal electrodes, depending on the direction of current flow, polarization can either inhibit (cathodal) or facilitate (anodal) function.

**Clinical Studies**

Preliminary research suggests that tDCS may enhance certain brain functions independent of mood; however, tDCS technology and its use in psychiatry are in the early stages of exploration. Research is focusing on its potential effectiveness in facilitating recovery from stroke and from certain forms of dementia.

**Future Directions**

Most of the current tDCS devices use large, saline solution–soaked electrodes. Future device development will most likely investigate electrode shape and contact material to optimize the intended clinical effects and further improve ease of use. However, basic questions of efficacy, indications, and dose–response relationships, as well as predictors of response, will need to be explored first.

**CRANIAL ELECTRICAL STIMULATION**

**Definition**

CES, like tDCS, uses a weak (1 to 4 mA) current. However, with CES the current is alternating. It is traditionally applied via saline-soaked, felt-covered electrodes clipped onto the earlobes. Other placement strategies are also being investigated.

**Mechanism of Action**

The exact mechanism of action has not been elicited, and there is no agreement among researchers on the predominant mode of action. Previous hypotheses proposed that the
stimulation with the alternating microcurrent affects the thalamic and hypothalamic brain tissue and facilitates the release of neurotransmitters. Claims have been made that through interaction with cell membranes, the stimulation produces changes in signal transduction associated with classical second-messenger pathways, including calcium channels and cyclic adenosine monophosphate (AMP). There are summary reports that CES causes increases in plasma serotonin, norepinephrine, dopamine, and monoamine oxidase type B (MAO<sub>B</sub>) in blood platelets and cerebrospinal fluid (CSF), as well as release of 5-hydroxy-indol-acetic acid (DHEA) and enkephalins and reduction of cortisol and tryptophan. However, most of these reports have not been validated through modern research.

**Side Effects**

It is believed that the CES stimulation is not harmful, primarily due to its low voltage power supply (9-V battery) and lack of any reported adverse event by the FDA. Local skin effects, as well as a general feeling of dizziness, have been reported, however, and the use of the device during pregnancy, in those with low blood pressure, or in people who have arrhythmias or pacemakers is not advised by device manufacturers.

**Clinical Studies**

In a meta-analysis by the Harvard School of Public Health, 18 human clinical trials were examined that used CES to treat depression, anxiety, drug addiction, insomnia, headache, and pain. The overall pooled result showed CES to be better than sham treatment for anxiety at a statistically significant level.

**Current Status in Treatment Algorithms, Patient Selection, and Dosing**

The use of CES has not been studied sufficiently in the United States, and it does not have a specific place in any algorithm of standard US psychiatric practice.

**Future Directions**

As with tDCS, basic issues of indications, patient selection, dose–response relationship, and efficacy are under active research and remain to be optimized.

**MAGNETIC SEIZURE THERAPY**

**Definition**

MST is a novel form of a convulsive treatment that is under development in several research institutions in the United States and Europe. The treatment uses an alternating magnetic field that crosses the scalp and the calvarium bone unaffected by their high electrical impedance, to in turn induce a more-localized electrical current in the targeted regions of the cerebral cortex than is possible with ECT. The aim is to produce a seizure
MST is a convulsive treatment, in many ways similar to ECT. It is performed under general anesthesia. It requires approximately the same preparation and infrastructure as ECT. However, MST is given using a modified TMS device, one that can administer higher output than the conventional TMS devices and thus relies on magnetic stimulation, unlike electric stimulation in ECT. The MST procedure is performed under general anesthesia with a muscle relaxant. MST is at the stage of clinical trials and is not FDA approved.

Mechanism of Action
Induction of a seizure is hypothesized to be the underlying event responsible for the likely multiple specific mechanisms of action of MST treatment. As in ECT, these are not fully understood. However, due to its focality, MST appears to represent a tool better suited than ECT to study the mechanisms of action of convulsive therapy through its potential of inducing seizures initiated in different regions of the brain.

Side Effects
Adverse effects from MST, like those of ECT, are largely connected to the risks associated with anesthesia and generalized seizure. In addition, the MST magnetic coil produces a clicking noise that may potentially affect hearing. To mitigate that risk and prevent any cumulative damage, earplugs should be worn by both the patient and members of the treating team. Studies suggest that MST results in less retrograde and anterograde amnesia than ECT, although this result should be replicated in a larger trial.

Current Status in Treatment Algorithms
No clinical algorithms exist for MST, given that it is still an investigational protocol and treatments outside of research are not FDA approved. Assuming that the hypothesis that MST can approach the efficacy of ECT (but with fewer side effects) is correct, this magnetically induced convulsive treatment will play an important role prior to referral for ECT.

Future Directions
MST is a novel treatment in early phases of clinical testing. Clinical treatment variables, including dosing, optimal coil placement, patient selection, and mechanisms of action, are the topics of ongoing and future studies.

VAGUS NERVE STIMULATION
Definition
VNS is the direct, intermittent electrical stimulation of the left cervical vagus nerve via an implanted pulse generator, usually in the left chest wall. The electrode is wrapped around the left vagus nerve in the neck and is connected to the generator subcutaneously.

**Mechanisms of Action**
The majority of the fibers contained in the left vagus are afferents. It is estimated that as many as 80 percent of these fibers are up-going afferents, and thus chronic stimulation of these nerve fibers predominantly changes activity in the brainstem nuclei such as the nucleus of the tractus solitarius and other neighboring nuclei (e.g., Raphe) that alter serotonergic activity in cortical and limbic structures. In addition, persistent stimulation of the vagal afferents is anticonvulsant, an effect that appears to depend on the norepinephrine-producing locus ceruleus.

**Side Effects and Contraindications**
To date, reasonably comprehensive literature confirms that VNS is generally well tolerated. The adverse events that are most frequently reported are voice alteration, dyspnea, and neck pain. Besides the risk of perioperative infection, the surgical implantation carries a small risk of vocal cord paralysis, bradycardia, or asystole.

**Current Status in Treatment Algorithms**
The FDA indicated VNS for the adjunctive long-term treatment of chronic or recurrent depression in patients 18 years or older experiencing a major depressive episode in the setting of unipolar or bipolar disease who have not had an adequate response to four or more adequate antidepressant treatments. Consultation with another clinician experienced with treatment-resistant depression and VNS is recommended.

VNS treatment success rates are lower than those with ECT. Its onset of action is also comparatively slow—typically an approximately 30 percent response rate is observed after 1 year. VNS may be worth considering, therefore, when patients have failed to respond to less invasive treatments, ECT was ineffective, or post-ECT relapse cannot be prevented with less invasive means. VNS might be helpful with longer-term relapse prevention, but results of controlled trials would be useful to guide practice.

**Patient Selection**
VNS is approved as an adjunctive long-term treatment for chronic or recurrent depressive episodes in adults with a major depressive episode who have not had a satisfactory response to four or more adequate antidepressant trials. The efficacy of VNS in other disorders is unknown.

ECT can be safely used in patients with an implant as long as the VNS generator is turned off during the convulsive treatment. This is needed because of the anticonvulsant effects of VNS. It remains to be studied whether VNS could be useful in relapse
Dosing

The optimal dosing for psychiatric applications of VNS is still largely an area of investigation. The published studies do not identify optimal dosing parameters like time on, time off, frequency, current, or pulse width. However, the epilepsy literature suggests that there is a threshold current for efficacy. Given current knowledge of VNS dosing, electrical current is typically increased up to greater than 1 mA and clinical benefit is assessed over several months. Because the adverse effects of VNS are known to be dose dependent, treatment parameters are often chosen to mitigate specific side effects. For example, lowering pulse width reduces neck pain, allowing patients to tolerate higher currents.

Future Directions

More research is required to establish the dose–response relationships for VNS. Future studies may explore optimal medication strategies to augment responses, test the potential role of VNS for long-term relapse prevention (e.g., after ECT), and study its mechanisms of action.

IMPLANTED CORTICAL STIMULATION

Definition

CBS is a novel neurosurgical approach in which electrodes are implanted over the surface of the cortex to provide electrical brain stimulation in a targeted superficial region. This approach is being studied for treatment of conditions like stroke, tinnitus, and treatment-resistant depression.

REFERENCES

30.3 Neurosurgical Treatments and Deep Brain Stimulation

After a long and checkered history, neurosurgical treatments for psychiatric illness have reemerged as a focus of great interest. Many still associate psychiatric neurosurgery with the bygone era of crude freehand “psychosurgery,” when prefrontal lobotomy saw wide and indiscriminate use. Those primitive operations, which predated modern psychopharmacology, yielded modest reductions in symptoms but were accompanied by unacceptable adverse effects. Over nearly five decades, techniques, and importantly, procedures and practices have evolved tremendously. First, ablative lesions are now accurately, precisely, and reproducibly placed in specific brain targets stereotactically guided by magnetic resonance imaging (MRI) and specialized software. Alternative methods include radiosurgery, which allows stereotactic lesion placement without craniotomy. Deep brain stimulation (DBS), while requiring craniotomy to implant stimulating electrodes in specific brain targets, is intentionally nonablative and allows flexible and reversible modulation of brain function. Second, strict criteria for patient selection are observed, and the process of determining appropriate candidacy has been formalized.

Currently, surgical intervention is predominantly reserved for patients with severe, incapacitating major depression or obsessive-compulsive disorder (OCD) who have failed an exhaustive array of standard treatments. Surgery is not approved unless a multidisciplinary committee reaches consensus regarding its appropriateness for a given candidate and the patient renders informed consent. Although a large body of clinical data has already been collected that indicates the effectiveness and safety of modern neurosurgical interventions, major centers providing these treatments continue to gather information prospectively, and controlled trials are under way or planned. With these advances in neurosurgical techniques and better
established selection criteria and long-term follow-up procedures, available data suggest that psychiatric neurosurgery yields substantial improvement in symptoms and functioning in approximately 40 to 70 percent of cases, with morbidity and mortality drastically lower than for earlier procedures.

Although lesion procedures have been influenced by theories implicating corticolimbic systems in disordered behavior, they were initially developed largely empirically. Although psychiatric neurosurgery is sometimes criticized for this reason, as for any clinical therapy, the relevant issues are safety and efficacy, not correction of pathophysiological processes that are not yet fully understood. However, in addition to the promise of modern lesion procedures and DBS as clinical treatments, clinicians permit testing of hypotheses derived from the results of lesions or from systematic human neuroimaging. Thus, psychiatric neurosurgery is now developing in a scientific context where translation of data between clinical results to cross-species anatomical, neuroimaging, and physiological studies of neural networks involved a promise to illuminate mechanisms of therapeutic action.

HISTORY

Trephination performed by ancient civilizations probably represents the earliest form of surgical intervention for psychopathology. In 1891 the first formal report of neurosurgical treatment in psychiatry was published, describing bilateral cortical excisions in demented and depressed patients, which yielded mixed results. After four decades in which little progress was made, in 1935 John Fulton and Charles Jacobsen presented their research on primate behavior following frontal cortical ablation. They observed that lobectomized chimpanzees showed reduction in “experimental neurosis” and were less fearful, while retaining an ability to perform complex tasks. Egaz Moniz, a renowned Portuguese neurologist, pioneered prefrontal leukotomy in collaboration with his neurosurgical colleague Almeida Lima. First by using absolute alcohol injections and subsequently by mechanical means with a leukotome, Moniz and Lima performed “psychosurgery” on 20 severely ill institutionalized patients; 14 were said to have exhibited worthwhile improvement. In an era of overflowing asylums and few effective treatments for chronic debilitating psychiatric illness, this mode of therapy was initially enthusiastically embraced, and Moniz won the 1949 Nobel Prize in Medicine or Physiology for this contribution.

From the mid-1930s until the emergence of the phenothiazines in the mid-1950s, these techniques proliferated globally. Walter Freeman, a neuropsychiatrist, was perhaps the most zealous promoter of psychosurgery in the United States. Pioneering a series of freehand procedures to achieve prefrontal lobotomy (i.e., severing the white matter connections between the prefrontal cortex and the rest of the brain), Freeman together with neurosurgeon James Watts reported on their first 200 cases by 1942. Although the benefits of the surgery were highlighted, others acknowledged a significant complication rate, including frontal lobe syndrome, seizures, and even deaths. At its peak, lobotomy was being performed on approximately 5,000 patients per year in the United States alone. A review of the results of 10,365 prefrontal lobotomies performed from 1942 to 1954 in Britain concluded that while 70 percent showed improvement, adverse effects included 6 percent mortality, seizures in 1 percent, and disinhibition syndromes in 1.5 percent. There were widespread reports of blunted personality and socially inappropriate behavior. In the late 1940s and early 1950s, recognition of these risks prompted attempts to develop modified stereotactic surgical procedures that might yield better results. For example, Ernest Spiegel and Henry Wycis, who began stereotactic neurosurgery in humans, reported in the 1940s that dorsomedial thalamotomies improved obsessive-compulsive symptoms. However, with the introduction of chlorpromazine
(Thorazine) in 1954, medical management of psychiatric illness became newly possible. Thus, despite the advent of stereotactic neurosurgical techniques and a continued high prevalence of severe, treatment-refractory psychiatric illness, psychiatric neurosurgery was all but abandoned in favor of nonsurgical therapies.

PATIENT SELECTION: INDICATIONS AND CONTRAINDICATIONS

Although limited reports have suggested efficacy across a broad range of psychiatric conditions and research is expanding rapidly, as of this writing the best established indications for psychiatric neurosurgery remain major depression and OCD. In evaluating candidates, several factors are considered:

1. **Primary diagnosis**: The patient must meet clinical criteria for the diagnostic indication, and this disorder should be a primary cause of the patient’s debility and suffering.

2. **Severity**: The patient must have chronic, severe, and debilitating illness; duration of the primary illness must exceed 1 year and typically exceeds 5 years. Severity is gauged on standardized instruments (e.g., patients with OCD typically have Yale-Brown Obsessive-Compulsive Scale scores of 25 to 30; patients with major depression typically have Beck Depression Inventory scores of 30 or higher), while debility should be indicated by a low level of functioning (e.g., a Global Assessment of Functioning score of 50 or less) and a poor quality of life.

3. **Adequacy of previous treatment**: Patients must have already undergone an exhaustive array of other available established treatments, which are documented in detail.

4. **Psychiatric comorbidity**: Appropriate treatment must have been rendered for any comorbid psychiatric disorder; the presence of psychoactive substance use or severe personality disorders are considered strong relative contraindications.

5. **Medical comorbidity and surgical fitness**: Structural brain lesions or significant central nervous system injuries are strong contraindications. Medical conditions that increase neurosurgical risks (e.g., cardiopulmonary disease) and age 65 years are relative contraindications for lesion procedures, while for DBS the relative age restriction might be older. A history of past seizures is a risk factor for perioperative seizures after lesion procedures and must be weighed in the overall risk–benefit assessment (again, data are currently less clear in this regard for psychiatric DBS).

6. **Access to postoperative care**: The psychiatric neurosurgery procedures themselves represent the beginning of a new episode of care. It is crucial that patients have access to adequate postoperative treatment, including a psychiatrist (typically the referring physician) who will accept responsibility for managing the case after discharge. Arrangements for postoperative care (e.g., intensive behavior therapy) should be confirmed ahead of time. Importantly, after lesion procedures, care can generally be delivered in standard treatment settings without the need for highly specialized psychiatric neurosurgery teams. For deep brain stimulation, access to such teams is essential over the long term. Once implanted, patients require clinical monitoring and device adjustment, which can be intensive and time-consuming, especially early in treatment. Device monitoring and replacements may need to occur...
on a relatively urgent basis. The continuing costs incurred can be substantial, and adequacy of third-party reimbursement needs to be ensured in advance to the extent possible. After either lesion procedures or DBS, family or significant others may be needed to support and accompany patients to follow-up care, similar to the level of support that is usually necessary during the intensive evaluation process.

7. Informed consent: Under no circumstances should psychiatric neurosurgery be performed on patients against their will. The patient must be able and willing to render an informed consent. Formal consent monitoring may be used to ensure that the consent process is adequate. In rare instances, these procedures are performed with assent of the patient and formal consent from a legal guardian. In this context, age less than 18 years also represents a relative contraindication.

POSTOPERATIVE CARE
Immediate postoperative care includes the standard medical and surgical considerations following any stereotactic neurosurgical procedure. Special attention is paid to signs or symptoms of potential surgical complications, including infection, hemorrhage, seizures, or altered mental status. A postoperative MRI should be obtained to document the placement and extent of lesions. Intensive postoperative psychiatric treatment is recommended since the efficacy of the surgery may rely on some synergy between the neurosurgical intervention itself and enhanced response to pharmacological or behavioral therapies. Although dosages of psychotropic medications may be reduced during the immediate perioperative period, the medication regimen should be readjusted as tolerated postoperatively. Moreover, in the case of OCD, intensive behavior therapy should be initiated as soon as possible, preferably within the first month postoperatively.

For DBS, electrode implantation is usually followed by a several-week delay to enable resolution of local edema and stabilization of other factors that might influence the response to stimulation. Then, systematic outpatient adjustment of stimulation parameters is performed before initial settings are determined. This is often a time-consuming process, lasting hours over 1 or more days. Ongoing protocols for DBS entail frequent follow-up, especially during the approximate 6 months after implantation, to enable optimization of stimulation parameters, monitoring of the patient, and coordination of other pharmacological and behavioral therapies.

LESION PROCEDURES
Although numerous approaches have been tried, four lesion procedures have evolved as the safest and most effective for treating psychiatric disorders. All four entail bilateral lesions and are performed using modern stereotactic methods.

Subcaudate Tractotomy
Subcaudate tractotomy was introduced by Geoffrey Knight in Great Britain in 1964 as one of the first attempts to limit
ANTERIOR CINGULOTOMY

Anterior cingulotomy remains the most commonly employed neurosurgical treatment for psychiatric disease in North America. The surgery is conducted under local anesthesia and two or three approximately 1-cc lesions are made on each side by thermocoagulation through bilateral burr holes. The target is within the anterior cingulate cortex (Brodmann areas 24 and 32), at the margin of the white matter bundle known as the cingulum. Originally, the placement of lesions was determined by ventriculography; however, since 1991, anterior cingulotomy has been conducted via MRI guidance. Approximately 40 percent of patients return several months following the first operation for a second procedure to extend the first set of lesions. The indications for anterior cingulotomy include major depression and OCD.

Limbic Leukotomy

Limbic leukotomy was introduced by Desmond Kelly and colleagues in England in 1973. The procedure combines the targets of subcaudate tractotomy and anterior cingulotomy. The lesions have typically been made via thermocoagulation or with a cryoprobe. Historically, the precise placement of the lesions was guided by intraoperative stimulation; pronounced autonomic responses were believed to designate the optimal lesion site. The indications for limbic leukotomy include major depression, OCD, and other severe anxiety disorders. More recently, there is also some evidence that this procedure might be beneficial for repetitive self-injurious behaviors or in the context of severe tic disorders.

ANTERIOR CAPSULOTOMY

Anterior capsulotomy or its newer variant, Gamma Knife (Elekta, Stockholm) capsulotomy, are used in Scandinavia, the United States, Belgium, Brazil, and elsewhere. The procedure places lesions within the anterior limb of the internal capsule, which impinges on the adjacent ventral striatum, thereby interrupting fibers of passage between prefrontal cortex and subcortical nuclei including the dorsomedial thalamus. Although the original anterior capsulotomy procedure is performed using thermocoagulation via burr holes in the skull, over the past 15 years capsulotomy has also been performed using the Gamma Knife as an alternative. This radiosurgical instrument makes craniotomy unnecessary. Typically, gamma capsulotomy lesions are smaller than those induced by thermocapsulotomy, remaining within the ventral portion of the anterior capsule. Hence, the term gamma ventral capsulotomy is coming into use to describe this procedure. In contrast to thermocapsulotomy, gamma ventral capsulotomy may be performed as an outpatient procedure, with an overnight hospital stay usually the most that is required. The relative advantages and disadvantages of this radiosurgical approach are the focus of ongoing research, including a current controlled study of gamma ventral capsulotomy for OCD, the first of its kind for a lesion procedure in psychiatry. Some data suggest, unsurprisingly, that the rates of neuropsychiatric adverse effects may be considerably lower for gamma ventral capsulotomy than for earlier procedures in which much larger tissue volumes were lesioned. Indications for anterior capsulotomy include major depression, OCD, and other severe anxiety disorders.
Deep Brain Stimulation

DBS for psychiatric illness is not a new idea, although the devices, surgical techniques, and theoretical models of relevant neurocircuitry have all advanced. The procedure involves placement of small-diameter brain “leads” (e.g., approximately 1.3 mm) with multiple electrode contacts into subcortical nuclei or specific white matter tracts. The surgeon drills burr holes in skull bone under local anesthesia and then places the leads, guided by multimodal imaging and precise stereotactic landmarking. Usually this is done bilaterally. The patient is typically sedated but awake during surgery. Later, the “pacemaker” (also known as an implantable neurostimulator or pulse generator) is implanted subdermally (e.g., in the upper chest wall) and connects it, via extension wires tunneled under the skin, to the brain leads. The goals of DBS are to achieve improved efficacy and more favorable adverse effect profiles in comparison with ablation. Because various combinations of electrodes can be activated, at adjustable polarity, intensity, and frequency, DBS allows more flexible modulation of brain function, referred to as neuromodulation. Thus, parameters can be optimized for individual patients, but the process, typically performed by a specially trained psychiatrist in the outpatient setting, can be quite time-consuming and requires attentive, long-term follow-up. In cases where no beneficial settings can be identified despite extensive efforts, the electrodes can be inactivated, and devices may be removed. In that event, devices are usually only partly explanted, with the brain electrodes left in place given the small risk of hemorrhage upon removal. The relative advantages and disadvantages of DBS are the focus of very active research.

TREATMENT OUTCOME

For all four contemporary ablative procedures, outcome cannot be fairly assessed for a considerable period postoperatively, which could extend from 6 months to 2 years. In the first two or three decades of this work, clinical reports usually employed measures of global improvement, such as the Pippard Postoperative Rating Scale, which rates outcomes as follows: (1) symptom free, (2) much improved, (3) slightly improved, (4) unchanged, and (5) worse. Most studies have operationalized significant improvement as categories 1 and 2. In addition, many of the reports employ a measure of symptom severity that is specific to the indication for the procedure (e.g., the Yale-Brown Obsessive-Compulsive Scale for OCD and the Beck Depression Inventory for major depression). The majority of studies focus on one or another of the procedures and are best reviewed according to surgical approach.

Outcome with Subcaudate Tractotomy

Significant improvement was seen in 68 percent of patients with major depression, 50 percent of patients with OCD, and 62.5 percent of patients with other anxiety disorders. Patients with schizophrenia, substance abuse, or personality disorders did poorly. Short-term side effects include transient headache and confusion or somnolence, which
typically resolve in less than 1 week. Patients are usually ambulatory by the third postoperative day. Transient disinhibition syndromes were common. In 1994, a large-scale review of 1,300 cases was conducted and concluded that the procedure enables 40 to 60 percent of patients to lead normal or near normal lives, with a reduction in suicide rate to 1 percent versus 15 percent in a similarly affected control group with major affective disorders.

**Outcome with Anterior Cingulotomy**

Significant improvement occurred in 62 percent of patients with affective disorders, 56 percent with OCD, and 79 percent with other anxiety disorders. Among patients with unipolar depression, 60 percent responded favorably; among patients with bipolar disorder, 40 percent responded favorably; and among patients with OCD, 27 percent were classified as responders with another 27 percent categorized as possible responders. Short-term side effects include headache, nausea, or difficulty with urination; however, these typically resolve within a few days. Patients are usually ambulatory within 12 hours following the operation and discharged on the third to fifth postoperative day. Over the past 10 years the practice of treating patients who experience perioperative seizures with chronic anticonvulsant therapy has been discontinued, and no cases of new onset recurrent seizures have been seen. Although patients have occasionally (5 percent or less) noted transient problems with memory, an independent analysis of 34 patients was performed and demonstrated no significant intellectual or behavioral impairments attributable to anterior cingulotomy; a subsequent study of 57 patients likewise found no evidence for lasting neurological or behavioral adverse effects.

**Outcome with Limbic Leukotomy**

Significant improvement occurred in 89 percent of patients with OCD, 78 percent with major depression, and 66 percent with other anxiety conditions. Short-term side effects include headache, lethargy or apathy, confusion, and lack of sphincter control, which may last from a few days to a few weeks. In particular, it is common for postoperative confusion to last at least several days, and patients are often not discharged in less than 1 week. There were no seizures and no deaths; however, one patient suffered severe memory loss due to improper lesion placement, and enduring lethargy was present in 12 percent of cases.

**Outcome with Anterior Capsulotomy**

**Thermocapsulotomy.** A favorable response occurred in 50 percent of those with OCD and 48 percent of those with major depression. Short-term side effects can include transient headache or incontinence. Postoperative confusion often lasts for up to 1 week. Recovery from gamma capsulotomy is swifter and characterized by less discomfort and virtually no confusion, but side effects from radiation exposure,
principally cerebral edema, may be delayed for up to 8 to 12 months. For the open capsulotomy, patients are typically ambulatory in a matter of hours to days following the operation, although the length of hospital stay may be influenced by the duration of confusion. Weight gain has been noted to be a common enduring side effect with a mean increase in mass of 10 percent.

**Gamma Ventral Capsulotomy.** Gamma capsulotomy was generally well tolerated and effective for patients with otherwise intractable OCD. Adverse events included cerebral edema and headache, small asymptomatic caudate infarctions, and possible exacerbation of preexisting bipolar mania. A therapeutic response, defined conservatively, was seen in 60 percent of over 50 patients receiving the most recent gamma capsulotomy procedure, in which pairs of lesions in the ventral capsule are made bilaterally, impinging on the ventral striatum. Therapeutic benefit was achieved over 1 to 2 years and was essentially stable by 3 years. Adverse effects of gamma ventral capsulotomy include significant radiation-induced edema, appearing months after the procedure, apparently due to a differential sensitivity to radiation that remains poorly understood. Long-term follow-up will be necessary to clarify risks and benefits of gamma ventral capsulotomy. The same applies to any neurosurgery, including lesion procedures and deep brain stimulation.

**Outcomes with DBS**

**Obsessive-Compulsive Disorder.** Over the past 10 years, four groups have collaborated closely on development of DBS at the ventral anterior limb of the internal capsule and adjacent ventral striatum (the VC/VS) for otherwise intractable OCD: Leuven/Antwerp, Butler Hospital/Brown University, the Cleveland Clinic, and the University of Florida. Long-term outcomes of open stimulation in 26 patients showed clinically significant symptom reductions and functional improvement in about two thirds of patients overall. Conservatively defined responses (35 percent or greater reductions on the Yale-Brown Obsessive-Compulsive Scale) were seen in one third of patients in the initial group, irrespective of study center, while the response rate was over 70 percent in the second and third patient cohorts treated. Development of psychiatric DBS is following the path of stimulation for movement disorders, where several targets have been pursued with therapeutic benefit. As in movement disorders, overlapping or converging effects of DBS at different anatomical sites on the neurocircuitry involved are likely and are a focus of active research. The same reasoning applies to DBS for depression.

**Major Depression.** A body of functional neuroimaging research implicates the subgenual cingulate cortex as a node in circuits involved in the normal experience of sadness, symptoms of depressive illness, and responses to depression treatments. Chronic DBS for up to 6 months was associated with sustained remission of depression in four of the six patients studied. Another line of research on DBS for depression was
prompted by the OCD research discussed above and also by the reported antidepressant
effects of anterior capsulotomy on which the VC/VC stimulation target was initially
based. The OCD patients, who had very high rates of comorbid depression,
characteristically responded to stimulation onset with mood enhancement and
reductions in nonspecific as well as OCD-related anxiety. Such effects were
accompanied, or even preceded, by improvements in social interaction and daily
functioning. Worsening in these same clinical domains was noted in some patients with
cessation of VC/VS stimulation. Moreover, DBS-induced changes in mood and
nonspecific anxiety often seemed to precede reductions in core OCD symptoms.

**Outcome Across Contemporary Neurosurgical Procedures**

Although the field is developing rapidly, the conclusion reached is that 40 to 70 percent
of carefully selected psychiatric patients should meaningfully benefit from
contemporary neurosurgical treatment. Twenty-five percent or more might be expected
to show outstanding improvement. Responses to ablative procedures have appeared
marginally superior for major depression than for OCD generally. The adverse-effect
profiles of this group of procedures are influenced by lesion size, the surgical approach,
and whether radiosurgical methods (in which the tempo of lesion development is very
slow versus thermocoagulation) are used. But adverse effects are greatly minimized in
comparison with procedures of the past. Although minor short-term side effects may be
common after some modern ablative procedures, severe or enduring adverse
consequences are relatively rare. These can include seizures in about 1 to 5 percent of
cases. Although frontal syndromes, confusion, or subtle cognitive deficits can still be
seen, overall cognitive function, as indicated by the standard intelligence quotient, is
generally enhanced, a finding that has been attributed to the overriding beneficial
effects of symptomatic improvement. Psychiatric neurosurgery likely reduces mortality,
as evidenced by data on comparative suicide rates. Nonetheless, patients who undergo
and fail to benefit from these procedures are at particularly high risk for completed
suicide. Therefore, as with any therapy, the potential risks and benefits of psychiatric
neurosurgery must be weighed against the potential risks and benefits of undergoing
this brand of treatment.

The advent of DBS in psychiatry has created tremendous interest and considerable
research activity. This therapy is intentionally nonablative, can be optimized for
individual patients, is reversible, and is based on devices that are (to varying degrees)
removable. DBS may therefore be accepted by patients who would not choose to
undergo lesion procedures (although the reverse is also true). With all of its advantages,
DBS requires that patients be treated by highly specialized teams willing and able to
provide long-term care. The logistics and expenses involved can represent significant
barriers. In contrast, psychiatric care can be delivered in standard treatment settings
after lesion procedures. However, although the relative risks of enduring adverse effects
after psychiatric DBS remain to be clearly established, at this stage ablative methods
appear to carry a greater potential for them. Because rates of adverse outcomes are low
when modern lesion procedures are performed at highly experienced centers, there may be a particularly strong rationale for referral of appropriate patients to such expert centers.

31.1 Introduction: Infant, Child, and Adolescent Development

The transactional nature of development in infancy, childhood, and adolescence, consisting of a continuous interplay between biological predisposition and environmental experiences, forms the basis of current conceptualizations of development. There is much evidence that observed developmental outcomes evolve from interactions between particular biological substrates and specific environmental events. For example, the serotonin transporter gene sensitizes a child with early adverse experiences of abuse or neglect to increased risk for later development of a depressive disorder. In addition, the degree of resilience and adaptation, that is, the ability to withstand adversity without negative effects, is likely to be mediated by endogenous glucocorticoids, cytokines, and neurotrophins. Thus, allostasis, the process of achieving stability in the face of adverse environmental events, results from interactions between specific environmental challenges and particular genetic backgrounds that combine to result in a response. It is widely accepted that adverse childhood experiences (ACEs) are likely to alter the trajectory of development in a given individual, and that during early development the brain is especially vulnerable to injury. Future studies may uncover windows of plasticity in older children and adolescents that affect vulnerability as well. Changes in both white matter and gray matter in the brains of adolescents are linked to increased acquisition of subtle social skills. Adolescents’ keen abilities, competencies, and interests in a host of technological advances—including the Internet, social media sites such as Facebook, Twitter, and Instagram, and smart phones, to name a few—shed some light on their potential to adapt to new and challenging demands.

Prenatal, Infant, and Child

The phases of development described in this section are defined as follows: prenatal is the time frame from conception to 8 weeks; the fetus, from 8 weeks to birth; infancy, from birth to 15 months; the toddler period, from 15 months to 2½ years; the preschool period, from 2½ years to 6 years; and the middle years, from 6 to 12 years.

Prenatal

Historically, the analysis of human development began with birth. The influence of endogenous and exogenous in utero factors, however, now requires that developmental
schemes take intrauterine events into consideration. The infant is not a tabula rasa, a smooth slate upon which outside influences etch patterns. To the contrary, the newborn has already been influenced by myriad factors that have occurred in the safety of the womb, the result of which has produced wide individual differences among infants. For example, the studies of Stella Chess and Alexander Thomas (described later) have demonstrated a wide range of temperamental differences among newborns. Maternal stress, through the production of adrenal hormones, also influences behavioral characteristics of newborns.

The time frame in which the development of the embryo and fetus occurs is known as the prenatal period. After implantation, the egg begins to divide and is known as an embryo. Growth and development occur at a rapid pace; by the end of 8 weeks, the shape is recognizably human, and the embryo has become a fetus. Figure 31.1-1 illustrates a sonogram of a 9-week and 15-week fetus in utero.

![Figure 31.1-1](image)

A. Sonogram of fetus at 9 weeks. B. Same fetus at 15 weeks. (Courtesy K.C. Attwell, M.D.)

The fetus maintains an internal equilibrium that, with variable effects, interacts continuously with the intrauterine environment. In general, most disorders that occur are multifactorial—the result of a combination of effects, some of which can be additive. Damage at the fetal stage usually has a more global impact than damage after birth, because rapidly growing organs are the most vulnerable. Boys are more vulnerable to developmental damage than girls are; geneticists recognize that in humans and animals, female fetuses show a propensity for greater biological vigor than male fetuses, possibly because of the second X chromosome in the female.

**Prenatal Life**

Much biological activity occurs in utero. A fetus is involved in a variety of behaviors that are necessary for adaptation outside the womb. For example, a fetus sucks on thumb and fingers; folds and unfolds its body, and eventually assumes a position in which its occiput is in an anterior vertex position, which is the position in which fetuses usually exit the uterus.
Behavior. Pregnant women are extraordinarily sensitive to prenatal movements. They describe their unborn babies as active or passive, as kicking vigorously or rolling around, as quiet when the mothers are active, but as kicking as soon as the mothers try to rest.

Women usually detect fetal movements 16 to 20 weeks into the pregnancy; the fetus can be artificially set into total body motion by in utero stimulation of its ventral skin surfaces by the 14th week. The fetus may be able to hear by the 18th week, and it responds to loud noises with muscle contractions, movements, and an increased heart rate. Bright light flashed on the abdominal wall of the 20-week pregnant woman causes changes in fetal heart rate and position. The retinal structures begin to function at that time. Eyelids open at 7 months. Smell and taste are also developed at this time, and the fetus responds to substances that may be injected into the amniotic sac, such as contrast medium. Some reflexes present at birth exist in utero: the grasp reflex, which appears at 17 weeks; the Moro (startle) reflex, which appears at 25 weeks; and the sucking reflex, which appears at about 28 weeks.

Nervous System. The nervous system arises from the neural plate, which is a dorsal ectodermal thickening that appears on about day 16 of gestation. By the sixth week, part of the neural tube becomes the cerebral vesicle, which later becomes the cerebral hemispheres (Fig. 31.1-2).

FIGURE 31.1-2
Formation of the neural tube and neural crest. These schematic illustrations follow the early development of the nervous system in the embryo. The drawings above are dorsal
views of the embryo; those below are cross sections. A. The primitive embryonic central nervous system (CNS) begins as a thin sheet of ectoderm. B. The first important step in the development of the nervous system is the formation of the neural groove. C. The walls of the groove, called neural folds, come together and fuse, forming the neural tube. D. The bits of neural ectoderm that are pinched off when the tube rolls up are called the neural crest, from which the peripheral nervous system (PNS) will develop. The somites are mesoderm that will give rise to much of the skeletal system and the muscles. (Reprinted from Bear MF, Conners BW, Paradiso MA, eds. Neuroscience: Exploring the Brain. 2nd ed. Philadelphia: Lippincott Williams & Wilkins. 2001:179, with permission.)

The cerebral cortex begins to develop by the 10th week, but layers do not appear until the sixth month of pregnancy; the sensory cortex and the motor cortex are formed before the association cortex. Some brain function has been detected in utero by fetal encephalographic responses to sound. The human brain weighs about 350 g at birth and 1,450 g at full adult development, a fourfold increase, mainly in the neocortex. This increase is almost entirely because of the growth in the number and branching of dendrites establishing new connections. After birth, the number of new neurons is negligible. Uterine contractions can contribute to fetal neural development by causing the developing neural network to receive and transmit sensory impulses.

**Pruning**

Pruning refers to the programmed elimination during development of neurons, synapses, axons, and other brain structures from the original number, present at birth, to a lesser number. Thus, the developing brain contains structures and cellular elements that are absent in the older brain. The fetal brain generates more neurons than it will need for adult life. For example, in the visual cortex, neurons increase in number from birth to 3 years of age, at which point they diminish in number. Another example is that the adult brain contains fewer neural connections than were present during the early and middle years of childhood. Approximately twice as many synapses are present in certain parts of the cerebral cortex during early postnatal life than during adulthood.

Pruning occurs to rid the nervous system of cells that have served their function in the development of the brain. Some neurons, for example, exist to produce neurotrophic or growth factors and are programmed to die—a process called apoptosis—when that function is fulfilled.

The implication of these observations is that the immature brain can be vulnerable in locations that lack sensitivity to injury later on. The developing white matter of the human brain before 32 weeks of gestation is especially sensitive to damage from hypoxic and ischemic injury and metabolic insults. Neurotransmitter receptors located on synaptic terminals are subject to injury from excessive stimulation by excitatory amino acids, (e.g., glutamate, aspartate), a process referred to as excitotoxicity. Research is proceeding on the implications of such events in the etiology of child and adult neuropsychiatric disorders such as schizophrenia.
Maternal Stress

Maternal stress correlates with high levels of stress hormones (epinephrine, norepinephrine, and adrenocorticotropic hormone) in the fetal bloodstream, which act directly on the fetal neuronal network to increase blood pressure, heart rate, and activity level. Mothers with high levels of anxiety are more likely to have babies who are hyperactive, irritable, and of low birth weight, and who have problems feeding and sleeping than are mothers with low anxiety levels. A fever in the mother causes the fetus’s temperature to rise.

Genetic Disorders

In many cases, genetic counseling depends on prenatal diagnosis. The diagnostic techniques used include amniocentesis (transabdominal aspiration of fluid from the amniotic sac), ultrasound examinations, x-ray studies, fetoscopy (direct visualization of the fetus), fetal blood and skin sampling, chorionic villus sampling, and α-fetoprotein screening. In about 2 percent of women tested, the results are positive for some abnormality, including X-linked disorders, neural tube defects (detected by high levels of α-fetoprotein), chromosomal disorders (e.g., trisomy 21), and various inborn errors of metabolism (e.g., Tay-Sachs disease and lipoidoses). Figure 31.1-3 illustrates hypertelorism of the eyes.

![Hypertelorism. Note the wide distance between the eyes, flat nasal bridge, and external strabismus. (Courtesy of Michael Malone, M.D. Children’s Hospital, Washington, D.C.)](image)

Some diagnostic tests carry a risk; for instance, about 5 percent of women who
undergo fetoscopy miscarly. Amniocentesis, which is usually performed between the 14th and 16th weeks of pregnancy, causes fetal damage or miscarriage in less than 1 percent of women tested. Fully 98 percent of all prenatal tests in pregnant women reveal no abnormality in the fetus. Prenatal testing is recommended for women older than 35 years of age and for those with a family history of a congenital defect.

Parental reactions to birth defects can include feelings of guilt, anxiety, or anger as their worst fears during the pregnancy are realized. Some degree of depression over the loss of the fantasized perfect child may be observed before the parents develop more active coping strategies. Termination of a pregnancy because of a known or suspected birth defect is an option chosen by some women.

**Maternal Drug Use**

**Alcohol.** Alcohol use in pregnancy is a major cause of serious physical and mental birth defects in children. Each year, up to 40,000 babies are born with some degree of alcohol-related damage. The National Institute on Drug Abuse (NIDA) reports that 19 percent of pregnant women used alcohol during their pregnancy, the highest rate being among white women.

Fetal alcohol syndrome (Fig. 31.1-4) affects about one third of all infants born to alcoholic women. The syndrome is characterized by growth retardation of prenatal origin (height, weight); minor anomalies, including microphthalmia (small eyeballs), short palpebral fissures, midface hypoplasia (underdevelopment), a smooth or short philtrum, and a thin upper lip; and central nervous system (CNS) manifestations, including microcephaly (head circumference below the third percentile), a history of delayed development, hyperactivity, attention deficits, learning disabilities, intellectual deficits, and seizures. The incidence of infants born with fetal alcohol syndrome is about 0.5 per 1,000 live births.
Photographs of children with “fetal-alcohol syndrome.” A. Severe case. B. Slightly affected child. Note in both children the short palpebral fissures and hypoplasia of the maxilla. Usually, the defect includes other craniofacial abnormalities. Cardiovascular defects and limb deformities are also common symptoms of the fetal alcohol syndrome. (From Langman J. Medical Embryology. 7th ed. Philadelphia: Williams & Wilkins; 1995:108, with permission.)

Some studies suggest that alcohol use during pregnancy may contribute to attention-deficit/hyperactivity disorder (ADHD). Animal experiments have shown that alcohol reduces the number of active dopamine neurons in the midbrain area, and ADHD is associated with reduced dopaminergic activity in the brain.

**Smoking.** Smoking during pregnancy is associated with both premature births and below-average infant birth weight. Some reports have associated sudden infant death syndrome (SIDS) with mothers who smoke.

**Other Substances.** Marijuana (used by 3 percent of all pregnant women) and cocaine (used by 1 percent) are the two most commonly abused illegal drugs, followed by heroin. Chronic marijuana use is associated with low infant birth weight, prematurity, and withdrawal-like symptoms, including excessive crying, tremors, and hyperemesis (severe and chronic vomiting). Crack cocaine use by women during pregnancy has been correlated with behavioral abnormalities such as increased irritability and crying and decreased desire for human contact. Infants born to mothers dependent on narcotics go through a withdrawal syndrome at birth.

Prenatal exposure to various prescribed medications can also result in abnormalities. Common drugs with teratogenic effects include antibiotics (tetracyclines), anticonvulsants (valproate [Depakene], carbamazepine [Tegretol], phenytoin [Dilantin]), progesterone-estrogens, lithium (Eskalith), and warfarin (Coumadin). Table 31.1-1 outlines the etiologies of malformations that may emerge during the first year of life.

INFANCY

The delivery of the fetus marks the start of infancy. The average newborn weighs about 3,400 g (7.5 lb.). Small fetuses, defined as those with a birth weight below the 10th percentile for their gestational age, occur in about 7 percent of all pregnancies. At the 26th to the 28th week of gestation, the prematurely born fetus has a good chance of survival. Arnold Gesell described developmental landmarks that are widely used in both pediatrics and child psychiatry. These landmarks outline the sequence of children’s motor, adaptive, and personal–social behavior from birth to 6 years (Table 31.1-2).

(Adapted from Arnold Gesell, M.D., and Stella Chess, M.D.)
Premature infants are defined as those with a gestation of less than 34 weeks or a birth weight less than 2,500 g (5.5 lb.). Such infants are at increased risk for learning disabilities, such as dyslexia, emotional and behavioral problems, mental retardation, and child abuse. With each 100 g increment of weight, beginning at about 1,000 g (2.2 lb.), infants have a progressively better chance of survival. A 36-week-old fetus has less chance of survival than a 3,000 g (6.6 lb) fetus born close to term. The differences between full-term and infants born prematurely are shown in Figure 31.1-5.

![Figure 31.1-5](image)

**FIGURE 31.1-5**
Contrast between full-term (A and B) and premature (C and D) infants. Note the limp sprawl of the baby in C and the difficulty in raising the head to clear the nose and mouth in D. (Reprinted from Stone LJ, Church J. *Childhood and Adolescence*. 4th ed. New York: Random House; 1979:7, with permission.)

Postmature infants are defined as infants born 2 weeks or more beyond the expected date of birth. Because pregnancy at term is calculated as extending 40 weeks from the last menstrual period and the exact time of fertilization varies, the incidence of postmaturity is high if based on menstrual history alone. The postmature baby typically has long nails, scanty lanugo, more scalp hair than usual, and increased alertness.

**Developmental Milestones in Infants**

**Reflexes and Survival Systems at Birth.** Reflexes are present at birth. They include the rooting reflex (puckering of the lips in response to perioral stimulation), the grasp reflex, the plantar (Babinski) reflex, the knee reflex, the abdominal reflexes, the
startle (Moro) reflex (Fig. 31.1-6), and the tonic neck reflex. In normal children, the grasp reflex, the startle reflex, and the tonic neck reflex disappear by the fourth month. The Babinski reflex usually disappears by the 12th month.

![Moro reflex](image)

**FIGURE 31.1-6**

Survival systems—breathing, sucking, swallowing, and circulatory and temperature homeostasis—are relatively functional at birth, but the sensory organs are incompletely developed. Further differentiation of neurophysiological functions depends on an active process of stimulatory reinforcement from the external environment, such as persons touching and stroking the infant. The newborn infant is awake for only a short period each day; rapid eye movement (REM) and non-REM sleep are present at birth. Other spontaneous behaviors include crying, smiling, and penile erection in males. Infants 1 day old can detect the smell of their mother’s milk, and those 3 days old distinguish their mother’s voice.

**Language and Cognitive Development.** At birth, infants can make noises, such as crying, but they do not vocalize until about 8 weeks. At that time, guttural or babbling sounds occur spontaneously, especially in response to the mother. The persistence and further evolution of children’s vocalizations depend on parental reinforcement. Language development occurs in well-delineated stages as outlined in Table 31.1-3.

<table>

</table>
By the end of infancy (about 2 years), infants have transformed reflexes into voluntary actions that are the building blocks of cognition. They begin to interact with the environment, to experience feedback from their own bodies, and to become intentional in their actions. By the end of the second year of life, children begin to use symbolic play and language.

Jean Piaget (1896–1980), a Swiss psychologist, observed the growing capacity of young children (including his own) to think and to reason. An outline of the Piaget’s stages of cognitive development is presented in Table 3.1-4.

Emotional and Social Development. By the age of 3 weeks, infants imitate the facial movements of adult caregivers. They open their mouths and thrust out their tongues in response to adults who do the same. By the third and fourth months of life, these behaviors are easily elicited. These imitative behaviors are believed to be the

precursors of the infant’s emotional life. The smiling response occurs in two phases: the first phase is endogenous smiling, which occurs spontaneously within the first 2 months and is unrelated to external stimulation; the second phase is exogenous smiling, which is stimulated from the outside, usually by the mother, and occurs by the 16th week.

The stages of emotional development parallel those of cognitive development. Indeed, the caregiving person provides the major stimulus for both aspects of mental growth. Human infants depend totally on adults for survival. Through warm and predictable interactions, an infant’s social and emotional repertoire expands with the interplay of caregivers’ social responses (Table 31.1-5).

In the first year, infants’ moods are highly variable and intimately related to internal states such as hunger. Toward the second two thirds of the first year, infants’ moods grow increasingly related to external social cues; a parent can get even a hungry infant to smile. When the infant is internally comfortable, a sense of interest and pleasure in the world and in its primary caregivers should prevail. Prolonged separation from the mother (or other primary caregiver) during the second 6 months of life can lead to depression that may persist into adulthood as part of an individual’s character.

**Temperamental Differences**

There are strong suggestions of inborn differences and wide variability in autonomic reactivity and temperament among individual infants. Chess and Thomas identified nine behavioral dimensions, in which reliable differences among infants can be observed.
Most temperamental dimensions of individual children showed considerable stability over a 25-year follow-up period, but some temperamental traits did not persist. This finding was attributed to genetic and environmental effects on personality. A complex interplay exists among the initial characteristics of infants, the mode of parental interactions, and children’s subsequent behavior. Observations of the stability and plasticity of certain temperamental traits support the importance of interactions between genetic endowment (nature) and environmental experience (nurture) in behavior.

### Attachment

Bonding is the term used to describe the intense emotional and psychological relationship a mother develops for her baby. Attachment is the relationship the baby develops with its caregivers. Infants in the first months after birth become attuned to social and interpersonal interaction. They show a rapidly increasing responsivity to the external environment and an ability to form a special relationship with significant primary caregivers—that is, to form an attachment. Table 31.1-7 lists the commonly observed attachment styles.

Harry Harlow. Harry Harlow studied social learning and the effects of social isolation in monkeys. Harlow placed newborn rhesus monkeys with two types of surrogate mothers—one a wire-mesh surrogate with a feeding bottle and the other a wire-mesh surrogate covered with terry cloth. The monkeys preferred the terry-cloth surrogates, which provided contact and comfort, to the feeding surrogate. (When hungry, the infant monkeys would go to the feeding bottle but then would quickly return to the terry-cloth surrogate.) When frightened, monkeys raised with terry-cloth surrogates showed intense clinging behavior and appeared to be comforted, whereas those raised with wire-mesh surrogates gained no comfort and appeared to be disorganized. The results of Harlow’s experiments were widely interpreted as indicating that infant attachment is not simply the result of feeding.

Both types of surrogate-reared monkeys were subsequently unable to adjust to life in a monkey colony and had extraordinary difficulty learning to mate. When impregnated, the female monkeys failed to mother their young. These behavioral peculiarities were attributed to the isolates’ lack of mothering in infancy.

John Bowlby. John Bowlby studied the attachment of infants to mothers and concluded that early separation of infants from their mothers had severe negative effects on children’s emotional and intellectual development. He described attachment behavior, which develops during the first year of life, as the maintenance of physical contact between the mother and child when the child is hungry, frightened, or in distress.
Mary Ainsworth. Mary Ainsworth expanded on Bowlby’s observations and found that the interaction between mother and baby during the attachment period influences the baby’s current and future behavior significantly. Many observers believe that patterns of infant attachment affect future adult emotional relationships. Patterns of attachment vary among babies; for example, some babies signal or cry less than others. Sensitive responsiveness to infant signals, such as cuddling the baby when it cries, causes infants to cry less in later months. Close bodily contact with the mother when the baby signals for her is also associated with the growth of self-reliance, rather than clinging dependence, as the baby grows older. Unresponsive mothers produce anxious babies.

Ainsworth also confirmed that attachment serves to reduce anxiety. What she called the secured base effect enables a child to move away from the attachment figure and explore the environment. Inanimate objects, such as a teddy bear or a blanket (called the transitional object by Donald Winnicott), also serve as a secure base, one that often accompanies children as they investigate the world. A growing body of literature derived from direct observation of mother–infant interactions and longitudinal studies has expanded on, and refined, Ainsworth’s original descriptions. Maternal sensitivity and responsiveness are the main determinants of secure attachment. But when the attachment is insecure, the type of insecurity (avoidant, anxious, or ambivalent) is determined by infant temperament. Overall, male infants are less likely to have secure attachments and are more vulnerable to changes in maternal sensitivity than are female infants.

The attachment of the firstborn child is decreased by the birth of a second, but it is decreased much more when the firstborn is 2 to 5 years of age when the younger sibling is born than when the firstborn is younger than 24 months. Not surprisingly, the extent of the decrease also depends on the mother’s own sense of security, confidence, and mental health.

Social Deprivation Syndromes and Maternal Neglect. Investigators, especially René Spitz, have long documented the severe developmental retardation that accompanies maternal rejection and neglect. Infants in institutions characterized by low staff-to-infant ratios and frequent turnover of personnel tend to display marked developmental retardation, even with adequate physical care and freedom from infection. The same infants, placed in adequate foster or adoptive care, exhibit marked acceleration in development.

Fathers and Attachment. Babies become attached to fathers as well as to mothers, but the attachment is different. Generally, mothers hold babies for caregiving, and fathers hold babies for purposes of play. Given a choice of either parent after separation, infants usually go to the mother, but if the mother is unavailable they turn to the father for comfort. Babies raised in extended families or with multiple caregivers are able to establish many attachments.
Stranger Anxiety. A developmentally expected fear of strangers is first noted in infants at about 26 weeks of age, and more fully developed by 32 weeks (8 months). At the approach of a stranger, infants cry and cling to their mothers. Babies exposed to only one caregiver are more likely to have stranger anxiety than babies exposed to a variety of caregivers. Stranger anxiety is believed to result from a baby’s growing ability to distinguish caregivers from all other persons.

Separation anxiety, which occurs between 10 and 18 months of age, is related to stranger anxiety but is not identical to it. Separation from the person to whom the infant is attached precipitates separation anxiety. Stranger anxiety, however, occurs even when the infant is in the mother’s arms. The infant learns to separate as it starts to crawl and move away from the mother, but the infant constantly looks back and frequently returns to the mother for reassurance.

Margaret Mahler (1897–1985) proposed a theory to describe how young children acquire a sense of identity separate from that of their mothers’. Her theory of separation–individuation was based on observations of the interactions of children and their mothers. Mahler’s stages of separation–individuation are outlined in Table 31.1-8.

Infant Care

Clinicians are now beginning to view infants as important actors in the family drama, ones who partly determine its course. Infants’ behavior controls mothers’ behavior, just as mothers’ behavior modulates infants’ behavior. A calm, smiling, predictable infant is a powerful reward for tender maternal care. A jittery, irregular, irritable infant tries a mother’s patience. When a mother’s capacity for giving is marginal, such infant traits
may cause her to turn away from her child and thus complicate the child’s already-troubled beginnings.

**Parental Fit**

Parental fit describes how well the mother or father relates to the newborn or developing infant; the idea takes into account temperamental characteristics of both parent and child. Each newborn has innate psychophysiological characteristics, which are known collectively as temperament. Chess and Thomas identified a range of normal temperamental patterns, from the difficult child at one end of the spectrum to the easy child at the other end.

Difficult children, who make up 10 percent of all children, have a hyperalert physiological makeup. They react intensely to stimuli (cry easily at loud noises), sleep poorly, eat at unpredictable times, and are difficult to comfort. Easy children, who make up 40 percent of all children, are regular in eating, eliminating, and sleeping; they are flexible, can adapt to change and new stimuli with a minimum of distress, and are easily comforted when they cry. The other 50 percent of children are mixtures of these two types. The difficult child is harder to raise and places greater demands on the parent than the easy child. Chess and Thomas used the term goodness of fit to characterize the harmonious and consonant interaction between a mother and a child in their motivations, capacities, and styles of behavior. Poor fit is likely to lead to distorted development and maladaptive functioning. A difficult child must be recognized, because parents of such infants often have feelings of inadequacy and believe that they are doing something wrong to account for the child’s difficulty in sleeping and eating and their problems comforting the child. In addition, most difficult children have emotional disturbances later in life.

**Good-Enough Mothering.** Winnicott believed that infants begin life in a state of nonintegration, with unconnected and diffuse experiences, and that mothers provide the relationship that enables infants’ incipient selves to emerge. Mothers supply a holding environment in which infants are contained and experienced. During the last trimester of pregnancy and for the first few months of a baby’s life, the mother is in a state of primary maternal preoccupation, absorbed in fantasies about, and experiences with, her baby. The mother need not be perfect, but she must provide good-enough mothering. She plays a vital role in bringing the world to the child and offering empathic anticipation of the infant’s needs. If the mother can resonate with the infant’s needs, the baby can become attuned to its own bodily functions and drives that are the basis for the gradually evolving sense of self.

**TODDLER PERIOD**

The second year of life is marked by accelerated motor and intellectual development. The ability to walk gives toddlers some control over their own actions; this mobility enables children to determine when to approach and when to withdraw. The acquisition
of speech profoundly extends their horizons. Typically, children learn to say “no” before they learn to say “yes.” Toddlers’ negativism is vital to the development of independence, but if it persists, oppositional behavior connotes a problem.

Learning language is a crucial task in the toddler period. Vocalizations become distinct, and toddlers can name a few objects and make needs known in one or two words. Near the end of the second year and into the third year, toddlers sometimes use short sentences. The pace of language development varies considerably from child to child, and although a small number of children are truly late developers, most child experts recommend a hearing test if the child is not making two-word sentences by age 2.

**Developmental Milestones in Toddlers**

**Language and Cognitive Development.** Toddlers begin to listen to explanations that can help them tolerate delay. They create new behaviors from old ones (originality) and engage in symbolic activities, for instance, using words and playing with dolls when the dolls represent something, such as a feeding sequence. Toddlers have varied capacities for concentration and self-regulation.

**Emotional and Social Development.** In the second year, pleasure and displeasure become further differentiated. Social referencing is often apparent at this age; the child looks to parents and others for emotional cues about how to respond to novel events. Toddlers show exploratory excitement, assertive pleasure, and pleasure in discovery and in developing new behavior (e.g., new games), including teasing and surprising or fooling the parent (e.g., hiding). The toddler has capacities for an organized demonstration of love, as when the toddler runs up and hugs, smiles, and kisses the parent at the same time, and of protest when the toddler turns away, cries, bangs, bites, hits, yells, and kicks. Comfort with family and apprehension with strangers may increase. Anxiety appears to be related to disapproval and the loss of a loved caregiver and can be disorganizing.

**Sexual Development.** Sexual differentiation is evident from birth, when parents start dressing and treating infants differently because of the expectations evoked by sex typing. Through imitation, reward, and coercion, children assume the behaviors that their cultures define as appropriate for their sexual roles. Children exhibit curiosity about anatomical sex. When their curiosity is recognized as healthy and is met with honest, age-appropriate replies, children acquire a sense of the wonder of life and are comfortable with their own roles. If the subject of sex is taboo and children’s questions are rebuffed, shame and discomfort may result.

*Gender identity,* the conviction of being male or female, begins to manifest at 18 months of age and is often fixed by 24 to 30 months. It was once widely believed that gender identity was primarily a function of social learning. John Money reported on children with ambiguous or damaged external genitalia who were raised as the sex
opposite to their chromosomal sex. Long-term follow-up of those individuals suggests that the major part of gender identity is innate and that rearing may not affect the genetic diathesis.

*Gender role* describes the behavior that society deems appropriate for one sex or another, and it is not surprising that significant cultural differences exist. There may be different expectations for boys and girls in what and with whom they play, their tone of voice, the expression of emotions, and how they dress. Nevertheless, some generalizations are possible. Boys are more likely than girls to engage in rough and tumble play. Mothers talk more to girls than to boys, and by the time the child is 2 years of age, fathers generally pay more attention to boys. Many educated, middle-class parents determined to raise nonsexist children are startled to see their children’s determined preference for sex-stereotyped toys: girls want to play with dolls, and boys with guns.

**Toilet Training.** The second year of life is a period of increasing social demands on children. Toilet training serves as a paradigm of the family’s general training practices; that is, the parent who is overly severe in the area of toilet training is likely to be punitive and restrictive in other areas also. Control of daytime urination is usually complete by the age of 2½, and control of nighttime urination is usually complete by the age of 4 years, when bowel control is usually accomplished. Since 1900, the pendulum has swung between extremes of permissiveness and control in toilet training. The trend in the United States has been toward delayed training, but in the last few years this trend appears to be shifting back to early training.

Toddlers may have sleep difficulties related to fear of the dark, which can often be managed by using a nightlight. Most toddlers generally sleep about 12 hours a day, including a 2-hour nap. Parents must be aware that children of this age may need reassurance before going to bed and that the average 2-year-old takes about 30 minutes to fall asleep.

**Parenting Challenges.** In infancy, the major responsibility for parents is to meet the infant’s needs in a sensitive and consistent fashion. The parental task in the toddler stage requires firmness about the boundaries of acceptable behavior and encouragement of the child’s progressive emancipation. Parents must be careful not to be too authoritarian at this stage; children must be allowed to operate for themselves and to learn from their mistakes and must be protected and assisted when challenges are beyond their abilities.

During the toddler period, children are likely to struggle for the exclusive affection and attention of their parents. This struggle includes rivalry, both with siblings and with one or another parent for the star role in the family. Although children are beginning to be able to share, they do so reluctantly. When the demands for exclusive possession are not resolved effectively, the result is likely to be jealous competitiveness in relationships with peers and lovers. The fantasies aroused by the struggle lead to fear of retaliation and to displacement of fear onto external objects. In an equitable, loving family a child
elaborates a moral system of ethical rights. Parents need to balance between punishment and permissiveness and set realistic limits on a toddler’s behavior.

PRESCHOOL PERIOD

The preschool period is characterized by marked physical and emotional growth. Generally, between 2 and 3 years of age, children reach half their adult height. The 20 baby teeth are in place at the beginning of the stage, and by the end they begin to fall out. Children are ready to enter school by the time the stage ends at age 5 or 6. They have mastered the tasks of primary socialization—to control their bowels and urine, to dress and feed themselves, and to control their tears and temper outbursts, at least most of the time.

The term preschool for the age group of 2½ to 6 years may be a misnomer; many children are already in school-like settings, such as preschool nurseries and day care centers, where working mothers must often place their children. Preschool education can be valuable, but stressing academic advancement too far beyond a child’s capabilities can be counterproductive.

Developmental Milestones in Preschoolers

Language and Cognitive Development. In the preschool period, children’s use of language expands, and they use sentences. Individual words have regular and consistent meanings at the beginning of the period, and children begin to think symbolically. In general, however, their thinking is egocentric; they cannot place themselves in the position of another child and are incapable of empathy. Children think intuitively and prelogically and do not understand causal relations.

Emotional and Social Behavior. At the start of the preschool period, children can express such complex emotions as love, unhappiness, jealousy, and envy, both preverbally and verbally. Their emotions are still easily influenced by somatic events, such as tiredness and hunger. Although they still think mostly egocentrically, children’s capacity for cooperation and sharing is emerging. Anxiety is related to loss of a person who was loved and depended on and to loss of approval and acceptance. Although still potentially disorganizing, anxiety can be tolerated better than in the past. Four-year-olds are learning to share and to have concern for others. Feelings of tenderness are sometimes expressed. Anxiety over bodily injury and the loss of a loved person’s approval is sometimes disruptive.

By the end of the preschool period, children have many relatively stable emotions. Expansiveness, curiosity, pride, and gleeful excitement related to the self and the family are balanced with coyness, shyness, fearfulness, jealousy, and envy. Shame and humiliation are evident. Capacities for empathy and love are developed but are fragile and easily lost if competitive or jealous strivings intervene. Anxiety and fears are related to bodily injury and loss of respect, love, and emerging self-esteem. Guilt
feelings are possible. Children between the ages of 3 and 6 years are aware of their bodies, and of differences between the sexes. In their play, doctor–nurse games allow children to act out their sexual fantasies. Their awareness of their bodies extends beyond the genitalia; they show a preoccupation with illness or injury, so much so that the period has been called “the Band-Aid phase.” Every injury must be examined and taken care of by a parent.

Children develop a division between what they want and what they are told to do. The division increases until a gap grows between their set of expanded desires, their exuberance at unlimited growth, and their parents’ restrictions; they gradually turn parental values into self-obedience, self-guidance, and self-punishment.

At the end of the preschool stage, the child’s conscience is evolving. The development of a conscience sets the tone for the moral sense of “right and wrong.” Until about 7 years of age, children typically experience rules as “absolute” and as existing for their own sake. They do not understand that more than one point of view on a moral issue may exist; a violation of the rules calls for absolute retribution—that is, children have the notion of immanent justice.

SIBLING RIVALRY. In the preschool period, children relate to others in new ways. The birth of a sibling (a common occurrence during this time) tests a preschool child’s capacity for further cooperation and sharing but may also evoke sibling rivalry, which is most likely to occur at this time. Sibling rivalry depends on child-rearing practice. Favoritism for any reason commonly aggravates such rivalry. Children who get special treatment because they are gifted, are defective in some way, or have a preferred gender are likely to receive angry feelings from their siblings. Experiences with siblings can influence growing children’s relationships with peers and authority; for example, a problem may result if the needs of a new baby prevent the mother from attending to a firstborn child’s needs. If not handled properly, the displacement of the firstborn can be a traumatic event.

PLAY. In the preschool years, children begin to distinguish reality from fantasy, and play reflects this growing awareness. Pretend games are popular and help test real-life situations in a playful manner. Dramatic play in which children act out a role, such as a housewife or a truck driver, is common. One-to-one play relationships advance to complicated patterns with rivalries, secrets, and two-against-one intrigues. Children’s play behavior reflects their level of social development.

Between 2½ and 3 years, children commonly engage in parallel play, solitary play alongside another child with no interaction between them. By age 3, play is often associative, that is, playing with the same toys in pairs or in small groups, but still with no real interaction among them. By age 4, children are usually able to share and engage in cooperative play. Real interactions and taking turns become possible.

Between 3 and 6 years of age, growth can be traced through drawings. A child’s first drawing of a human being is a circular line with marks for the mouth, nose, and eyes; ears and hair are added later; arms and stick-like fingers appear next; and then legs
IMAGINARY COMPANIONS. Imaginary companions most often appear during preschool years, usually in children with above-average intelligence and usually in the form of persons. Imaginary companions may also be things, such as toys that are anthropomorphized. Some studies indicate that up to 50 percent of children between the ages of 3 and 10 years have imaginary companions at one time or another. Their significance is not clear, but these figures are usually friendly, relieve loneliness, and reduce anxiety. In most instances, imaginary companions disappear by age 12, but they can occasionally persist into adulthood.

MIDDLE YEARS
The period between age 6 and puberty is often called the middle years. During this time, children enter elementary school. The formal demands for academic learning and accomplishment become major determinants of further personality development.

Developmental Milestones in School-age Children

Language and Cognitive Development. In the middle years, language expresses complex ideas with relations among several elements. Logical exploration tends to dominate fantasy, and children show an increased interest in rules and orderliness and an increased capacity for self-regulation. During this period, children’s conceptual skills develop, and thinking becomes organized and logical. The ability to concentrate is well established by age 9 or 10, and by the end of the period, children begin to think in abstract terms. Improved gross motor coordination and muscle strength enable children to write fluently and draw artistically. They are also capable of complex motor tasks and activities, such as tennis, gymnastics, golf, baseball, and skateboarding.

Recent evidence has shown that changes in thinking and reasoning during the middle years result from maturational changes in the brain. Children are now capable of increased independence, learning, and socialization. Theorists consider moral development a gradual, stepwise process spanning childhood, adolescence, and young adulthood.

In the middle years, both girls and boys make new identifications with other adults, such as teachers and counselors. These identifications may so influence girls that their goals of wanting to marry and have babies, as their mothers did, may be combined with a desire for a career or may be postponed or abandoned entirely.

Girls who cannot identify with their mothers or whose fathers are overly attached may
become fixated at about a 6-year-old level; as a result, they may fear men or women or both or become seductively close to them. In either case, such girls may not be seen as normal during the school-age years. A similar situation can occur in boys who have been unable to identify successfully with fathers who were aloof, brutal, or absent. Perhaps his mother prevented a boy from identifying with his father by being overprotective or by binding the son too closely to her. As a result, boys may enter this period with a variety of problems. They may be fearful of men, unsure of their sense of masculinity, or unwilling to leave their mothers (sometimes manifested by a school phobia); they may lack initiative and be unable to master school tasks, thus incurring academic problems.

The school-age period is a time when peer interaction assumes major importance. Interest in relationships outside the family takes precedence over those within the family. Nevertheless, a special relationship exists with the same-sex parent, with whom children identify and who is now an ideal and a role model.

Empathy and concern for others begin to emerge early in the middle years; by the time children are 9 or 10, they have well-developed capacities for love, compassion, and sharing. They have a capacity for long-term, stable relationships with family, peers, and friends, including best friends. Emotions about sexual differences begin to emerge as either excitement or shyness with the opposite sex. School-age children prefer to interact with children of the same sex. Although the middle years have sometimes been referred to as a latency period—a moratorium on psychosexual exploration and play until the eruption of sexual impulses with puberty—it is now recognized that a considerable amount of sexual interest continues through these years. Sex play and curiosity are common, especially among boys, but also among girls. Boys compare genitals and sometimes engage in group or mutual masturbation. An interest in anal humor and toilet jokes is often seen. Children this age often start using sexual and excretory words as expletives.

**BEST FRIEND.**  
Harry Stack Sullivan postulated that a buddy, or best friend, is an important phenomenon during the school years. By about 10 years of age, children develop a close same-sex relationship, which Sullivan believed is necessary for further healthy psychological growth. Moreover, Sullivan believed that the absence of a chum during the middle years of childhood is an early harbinger of schizophrenia.

**SCHOOL REFUSAL.**  
Some children refuse to go to school at this time, generally because of separation anxiety. A fearful mother may transmit her own fear of separation to a child, or a child who has not resolved dependence needs panics at the idea of separation. School refusal is usually not an isolated problem; children with the problem typically avoid many other social situations.

**Sex Role Development**

Persons’ sex roles are similar to their gender identity; persons see themselves as male or female. The sex role also involves identification with culturally acceptable masculine or feminine ways of behaving; but changing expectations in society (particularly in the
Parents react differently to their male and female children. Independence, physical play, and aggressiveness are encouraged in boys; dependence, verbalization, and physical intimacy are encouraged in girls. Nowadays, however, boys are encouraged to verbalize their feelings and to pursue interests traditionally associated with girls, whereas girls are encouraged to pursue careers traditionally dominated by men and to participate in competitive sports. As society grows more tolerant in its expectations of the sexes, roles become less rigid, and opportunities for boys and girls enlarge and broaden.

Biologically, boys are more physically aggressive than girls; and parental expectations, particularly the expectations of fathers, reinforce this trait. Differences also exist between boys and girls in the influence of persons outside the family. Girls tend to respond to the expectations and opinions of girls and of teachers of either sex, but to ignore boys. Boys, on the other hand, tend to respond to other boys, but to ignore girls and teachers.

Dreams and Sleep

Children’s dreams can have a profound effect on behavior. During the first year of life, when reality and fantasy are not yet fully differentiated, dreams may be experienced as if they were, or could be, true. At age 3, many children believe dreams are shared directly by more than one person, but most 4-year-olds understand that dreams are unique to each person. Children view dreams either with pleasure or, as is most often reported, with fear. The dream content should be seen in connection with children’s life experience, developmental stage, mechanisms used during dreaming, and sex.

Disturbing dreams peak when children are 3, 6, and 10 years of age. Two-year-old children may dream about being bitten or chased; at the age of 4, they may have many animal dreams and also dream of persons who either protect or destroy. At age 5 or 6, dreams of being killed or injured, of flying and being in cars, and of ghosts become prominent; the role of conscience, moral values, and increasing conflicts are concerned with these themes. In early childhood, aggressive dreams rarely seem to occur; instead, dreamers are in danger, a state that perhaps reflects children’s dependent position. By about the age of 5, children realize that their dreams are not real; before then, they believed them to be real events. By age 7, children know that they create their dreams themselves.

Between the ages of 3 and 6 years, children normally want to keep their bedroom door open or to have a nightlight, so that they can either maintain contact with their parents or view the room in a realistic, nonfearful way. At times, children resist going to sleep to avoid dreaming. Disorders associated with falling asleep, therefore, are often connected with dreaming. Children often create rituals to protect themselves in the withdrawal from the world of reality into the world of sleep. Parasomnias, such as sleepwalking, sleep talking, enuresis (bed-wetting), and night terrors, are common at
They usually occur during stage 4 sleep when dreaming is minimal, and they do not indicate emotional trouble or underlying psychopathology. Most children grow out of parasomnias by adolescence.

Periods of REM occur about 60 percent of the time during the first few weeks of life, a period when infants sleep two thirds of the time. Premature babies sleep even longer than full-term babies, and a greater proportion of their sleep is REM sleep. The sleep–wake cycle of newborns is about 3 hours long. Among adults, the dream-to-sleep ratio is stable: 20 percent of sleeping time is spent dreaming. Even newborns have brain activity similar to that of the dreaming state.

**Birth Spacing**

For women in the United States, 10 percent of conceptions that lead to live births are considered unwanted, and 20 percent are wanted but considered ill timed.

Children born close together have higher rates of premature or underweight births, and malnutrition; they develop more slowly and are at increased risk of contracting and dying from childhood infectious diseases. Studies have shown when a child is born 3 to 5 years after a previous birth, health risks are reduced for both mother and child. Compared with 24- to 29-month intervals, children born in 36- to 41-month intervals are associated with a 28 percent reduction in stunting and a 29 percent reduction of low birth weight. Women who have children at 27- to 32-month intervals are 1.3 times more likely to avoid anemia, 1.7 times more likely to avoid third-trimester bleeding, and 2.5 times more likely to survive childbirth.

**Birth Order**

The effects of birth order vary. Firstborn children are often more highly valued and given more attention than subsequent children. Firstborn children appear to be more achievement oriented and motivated to please their parents than subsequent children born to the same parents. Some studies show that people in certain competitive occupational areas, such as architecture, accounting, and engineering, tend to be firstborn children.

Second and third children have the advantage of their parents’ previous experience. Younger children also learn from their older siblings. For example, they may show more sophisticated use of pronouns at an earlier age than firstborns did. When children are spaced too closely, however, there may not be enough time for each child. The arrival of new children in the family affects not only the parents but also the siblings. Firstborn children may resent the birth of a new sibling, who threatens their sole claim on parental attention. In some cases, regressive behavior, such as enuresis or thumb-sucking, occurs.

According to Frank Sulloway, firstborn children tend to be conservative and conformists; by contrast, youngest children tend to be independent and rebellious in regard to family and cultural norms. Sulloway found that a high proportion of prominent persons were lastborn children. He ascribes these differences to birth order.
and suggests that each child develops personality traits to fit an unfilled slot in the family. His findings need to be replicated.

**Children and Divorce**

Many children live in homes in which divorce has occurred. Approximately 30 to 50 percent of all children in the United States live in homes in which one parent (usually the mother) is the sole head of the household, and 61 percent of all children born in any given year can expect to live with only one parent before they reach the age of 18 years. A child’s age at the time of the parents’ divorce affects the child’s reaction to the divorce. Immediately after a divorce, an increase in behavioral and emotional disorders appears in all age groups. Infants do not understand anything about separation or divorce; however, they do notice changes in their parents’ responses to them and may experience changes in their eating or sleeping patterns; have bowel problems; and seem more fretful, fearful, or anxious. Children 3- to 6-years of age may not understand what is happening, and those who do understand often assume that they are somehow responsible for the divorce. Older children, especially adolescents, comprehend the situation and may believe that they could have prevented the divorce had they intervened in some way, but they are still hurt, angry, and critical of their parents’ behavior.

Some children harbor the fantasy that their parents will be reunited in the future. Such children may show animosity toward a parent’s real or potential new mate because they are faced with the reality that reconciliation between their parents is not taking place. Adaptation to the effects of divorce in children typically takes several years; however, up to about one third of children from divorced homes may have lasting psychological trauma. Among boys, physical aggression is a common sign of distress. Adolescents tend to spend more time away from the parental home after the divorce. Children who adapt best to divorce are typically in a situation in which both parents make genuine efforts to spend time and relate to the child despite the child’s potential anger about the divorce. To facilitate adaptation in children, a divorced couple who are amicable, and avoid arguing with one another is most likely to succeed. Table 31.1-9 lists potential psychological effects of divorce on children.

| Table 31.1-9 |
| Effects of Divorce on Children |
Stepparents. Although there are many different scenarios that may occur after a divorce and remarriage, several potential scenarios have been outlined in Table 31.1-10. These include: (1) Neo-traditional, (2) Romantic, and (3) Matriarchal. When remarriage occurs, children must learn to adapt to the stepparent and to the “blended” family. Adaptation is often challenging, especially when a child feels that a stepparent is nonsupportive, resents the stepchild, or favors his or her own natural children. Of stepfamilies, 25 percent tend to dissolve within the first 2 years, whereas 75 percent grow to find a new balance in their blended family. A biological child born to a new couple with a stepchild already in the home may receive more attention than the stepchild, leading to sibling rivalry. After 5 years, about 20 percent of adolescents in step-families suggest that they move out and try living with their other biological parent.

Table 31.1-10
Types of Step-Families

(Data adapted from Americans for Divorce Reform, Arlington, Virginia. Table by Nitza Jones.)
Family Factors in Child Development

Family Stability. Parents and children living under the same roof in harmonious interaction is the expected cultural norm in Western society. Within this framework, childhood development presumably proceeds most expeditiously. Deviations from the norm, such as divorced- and single-parent families, are associated with a broad range of problems in children, including low self-esteem, increased risk of child abuse, and increased incidence of divorce when they eventually marry, and increased incidence of mental disorders, particularly depressive disorders and antisocial personality disorder as adults. Why some children from unstable homes are less affected than others (or even immune to these deleterious effects) is of great interest. Michael Rutter has postulated that vulnerability is influenced by sex (boys are more affected than girls), age (older children are less vulnerable than younger ones), and inborn personality characteristics. For example, children who have a placid temperament are less likely to be victims of abuse within a family than are hyperactive children; by virtue of their placidity, they may be less affected by the emotional turmoil surrounding them.

Adverse Events. It is now well known that significant adverse events, especially in early childhood such as sexual and physical abuse, neglect, or loss of a parent, interact with genetic background in a given child and influences the trajectory of development. For example, as mentioned earlier early severe maltreatment such as sexual abuse increases the risk of multiple psychosocial difficulties and emergence of many psychiatric disorders. Among young maltreated children, those with particular genetics, that is, who have the “short” variant of the serotonin transporter gene (short 5-HTTLPR polymorphism) are significantly more vulnerable to chronic depression in adulthood. This example of specific gene–environment interaction plays an important role in a child’s development as well as in the risk for future psychopathology. Current investigations are also seeking insight into what factors lead to resilience in youth who have been exposed to adverse events, yet maintain allostasis, that is, stability in the face of stressful events. Hormones of the adrenal glands, thyroid, gonads, as well as
metabolic hormones play a role on the brain’s ability to maintain stability upon exposure to stress, and the prefrontal cortex, hippocampus, and amygdala play critical roles in regulating emotionality, aggression, and resilience.

**Day Care Centers.** The role of day care centers for children is under continuous investigation, and various studies have produced different results. One study found that children placed in day care centers before the age of 5 are less assertive and less effectively toilet trained than home-reared children. Another study found children in day care to be more advanced in social and cognitive development than children who were not in day care. The National Institute of Child Health and Human Development reported that 4½ year olds who had spent more than 30 hours a week in child care were more demanding, more aggressive, and more noncompliant than those raised at home and showed higher cognitive skills, particularly in math and reading. These same children who were tracked through the third grade continued to score higher in math and reading skills but had poorer work habits and social skills. The researchers were careful to note that this behavior was within the normal range, however.

All studies of day care must take into account the quality of both the day care center and the homes from which children come. For example, a child from a disadvantaged home may be better off at a day care center than a child from an advantaged home. Similarly, a woman who wishes to leave the home to work for financial or other reasons and cannot do so may resent being forced to remain in the home in a child-rearing role, which may adversely affect the child.

**Parenting Styles.** The ways in which children are raised vary considerably between and within cultures. Rutter has clustered the diversity into four general styles. Subsequent research has confirmed that certain styles tend to correlate with certain behavior in the children, although the outcomes are by no means absolute. The authoritarian style, characterized by strict, inflexible rules, can lead to low self-esteem, unhappiness, and social withdrawal. The indulgent-permissive style, which includes little or no limit setting coupled with unpredictable parental harshness, can lead to low self-reliance, poor impulse control, and aggression. The indulgent-neglectful style, one of noninvolvement in the child’s life and rearing, puts the child at risk for low self-esteem, impaired self-control, and increased aggression. The authoritative-reciprocal style, marked by firm rules and shared decision-making in a warm, loving environment, is believed to be the style most likely to result in self-reliance, self-esteem, and a sense of social responsibility.

**Development and Expression of Psychopathology**
The expression of psychopathology in children can be related to both age and developmental level. Specific developmental disorders, particularly developmental language disorders, often are diagnosed in the preschool years. Delayed development of language is a common parental concern. Children who do not use words by 18 months
or phrases by 2½ to 3 years may need assessment, particularly if they do not appear to understand normal verbal cues or much language at all. Mild mental retardation or specific learning problems often are not diagnosed until after the child begins elementary school. Disruptive behavior disorder will become apparent at that time as the child begins to interact with peers. Similarly, attention-deficit disorders are only diagnosed when the demands for sustained attention are made in school. Other conditions, particularly schizophrenia and bipolar disorder, are rare in preschool and school-aged children.

**ADOLESCENCE**

Adolescence, marked by the physiological signs and surging sexual hormones of puberty, is the period of maturation between childhood and adulthood. Adolescence is a transitional period in which peer relationships deepen, autonomy in decision-making grows, and intellectual pursuits and social belonging are sought. Adolescence is largely a time of exploration and making choices, a gradual process of working toward an integrated concept of self. Adolescents can best be described as “works in progress,” characterized by increasing ability for mastery over complex challenges of academic, interpersonal, and emotional tasks, while searching for new interests, talents, and social identities. A body of growing literature of the specific mechanisms of brain development in adolescence has increased our understanding of broadening social skills in adolescents, in addition to the three expected developmental changes in adolescence: increased risk taking, increased sexual behavior, and a move toward peer affiliation rather than primary family attachment. The total cortical gray matter is at its peak at about age 11 years in girls and 13 years in boys, which enhances the ability to understand subtle social situations, control impulses, make long range plans, and think ahead. White matter volume increases throughout childhood and adolescence, which may allow for increased “connectivity,” thereby enhancing the abilities of adolescents to acquire new competencies, such as those needed to master today’s technology.

**What is Normal Adolescence?**

The concept of normality in adolescent development refers to the degree of psychological adaptation that is achieved while navigating the hurdles and meeting the milestones characteristic of this period of growth. For up to approximately 75 percent of youth, adolescence is a period of successful adaptation to physical, cognitive, and emotional changes, largely continuous with their previous functioning. Psychological maladjustment, self-loathing, disturbance of conduct, substance abuse, affective disorders, and other impairing psychiatric disorders emerge in approximately 20 percent of the adolescent population.

Adolescent adjustment is continuous with previous psychological function; thus, psychologically disturbed children are at greater risk for psychiatric disorders during adolescence. Adolescents with psychiatric disorders are at increased risk for greater conflicts with families and for feeling alienated from their families. Although up to 60
percent of adolescents endorse occasional distress, or a psychiatric symptom, this group of adolescents functions well academically and with peers and describes themselves as generally satisfied with their lives.

The developmentalist Erik Erikson characterizes the normative task of adolescence as identity versus role confusion. The integration of past experiences with current changes takes place in what Erikson terms ego identity. Adolescents explore various aspects of their psychological selves by becoming fans of heroes, or other well-known musical or political idols. Some adolescents appear consumed by their identification with a particular idol, whereas others are more moderate in their expression. Adolescents who feel accepted by a peer group and are involved in a variety of activities are less likely to become consumed by adoration of an idol. Adolescents who are socially isolated, feel socially rejected, and become overly identified with an idol to the exclusion of all other activities are at greater risk for serious emotional problems and require psychiatric intervention.

Erickson uses the term moratorium to describe that interim period between the concrete thinking of childhood and a more evolved complex ethical development. Erikson defines identity crisis as a normative part of adolescence in which adolescents pursue alternative behaviors and styles and, then, successfully mold these different experiences into a solid identity. A failure to do so would result in identity diffusion, or role confusion, in which the adolescent lacks a cohesive or confident sense of identity. Adolescence is the time to bond with peers, experiment with new beliefs and styles, fall in love for the first time, and explore creative ideas for future endeavors.

Most adolescents go through this developmental process with optimism, develop good self-esteem, maintain good peer relationships, and sustain basically harmonious relationships with their families.

**Stages of Adolescence**

**Early Adolescence.** Early adolescence, from 12 to 14 years of age, is the period in which the most striking initial changes are noticed—physically, attitudinally, and behaviorally. Growth spurts often begin in these years for boys, whereas girls may have already had rapid growth for 1 to 2 years. At this stage, boys and girls begin to criticize usual family habits, insist on spending time with peers with less supervision, have a greater awareness of style and appearance, and may question previously accepted family values. A new awareness of sexuality may be displayed by increased modesty and embarrassment with their current physical development or may exhibit itself in an increased interest in the opposite sex.

Early adolescents engage in subtle or overt displays of their growing desire for autonomy, sometimes with challenging behaviors toward authority figures, including teachers and school administrators, and exhibit disdain for rules themselves. At this age, some adolescents begin to experiment with cigarettes, alcohol, and marijuana.

During early adolescence, there is normal variation in when new defining behaviors are acquired. Overall, although many early adolescents make new friends and modify
their public image, most maintain positive connections to family members, old friends, and their family’s values. However, early adolescence has been viewed as a time of overwhelming turmoil, during which there is a dramatic rejection of family, friends, and lifestyle, resulting in a powerful alienation of the adolescent.

Jake, a 13-year-old adolescent, had just started the 8th grade. In the past, he has been a jovial, fun-loving, and cooperative student, but this year he found the school rules increasingly irritating and felt that his teachers were too strict. He had always been a good student while putting in a minimum of work. His older brother Sean, now in 11th grade, had established himself as a compliant, well-liked, and well-behaved student who always put maximal effort into school projects in the same school, so Jake was compared with his brother on a regular basis by many teachers. Jake resented these comparisons because, unlike his brother, whom Jake felt was a “nerd,” Jake was more rebellious, took more risks, and made friends with more popular peers. To distinguish himself from his older brother in school and at home, Jake began to challenge the rules at school, stating that they were “stupid” and “meaningless.” Jake began to cut classes, to stay out late, and to experiment with alcohol and marijuana. He rejected his best friends from 6th and 7th grade, and began to hang out with peers who were more daring. When Jake was at home, he was able to relate to his older brother Sean only when they played basketball and video games.

Jake’s grades began to deteriorate only slightly, but his parents noticed that on his report cards, his effort and behavior were rated as unsatisfactory. During the second month of school, Jake’s parents received a phone call that Jake was going to be suspended due to possession of a small amount of marijuana on the school grounds during recess. During a subsequent meeting with the assistant principal and school counselor, Jake argued that the suspension was unfair because his grades were still good, and did not understand why his marijuana possession had triggered a suspension. When confronted with the fact that he had not only broken the school rules, but also violated the law, and that he was fortunate because the school did not involve the police, Jake became angry and continued to insist that he was being treated unfairly. He also blurted out that all of his teachers and his parents favored his older brother Sean, and treated him like a second-class citizen. Jake was suspended for 5 days, but the school indicated that they would report the incident to the police unless Jake and his family initiated immediate counseling.

Jake begrudgingly began psychotherapy and entered into a weekly therapy group specializing in substance use, for teens. Jake’s parents also sought therapy to work on becoming more unified in their parenting. Jake remained in psychotherapy for the next 1½ years, during which time his attitude and reasoning style changed and evolved considerably. At age 15, Jake was able to understand why his school had suspended him for possession of marijuana and came to appreciate their willingness to give him the chance to seek counseling, rather than be turned over to the police. Over time, Jake was able to admit the dangers of using drugs, and took responsibility
for his ill-advised behaviors. Alcohol and drug use continued to be a focus of his therapy and, by 15, Jake had virtually lost interest in alcohol, and admitted to smoking marijuana rarely at parties. Jake became more open to making friends with a variety of peers, and he disclosed that he liked himself better now than when he was 13. He now treated his brother respectfully when alone or with friends, and he felt that his parents appreciated him for “who he was.” (Courtesy of Caroly S. Pataki, M.D.).

Middle Adolescence. During the middle phase of adolescence (roughly between the ages of 14 and 16), adolescents’ lifestyles may reflect their efforts to pursue their own stated goals of being independent. Their abilities to combine abstract reasoning with realistic decision-making and the application of social judgment is put to the test in this phase of adolescent development. In this phase, sexual behavior intensifies, making romantic relationships more complicated, and self-esteem becomes a pivotal influence on positive and negative risk-taking behaviors.

In this phase of development, adolescents tend to identify with a group of peers who become highly influential in their choices of activities, styles, music, idols, and role models. Adolescents’ underestimation of the risks associated with a variety of recreational behaviors and their sense of “omnipotence,” mixed with their drive to be autonomous, frequently cause some conflict with parental requests and expectations. For most teens, the process of defining themselves as unique and different from their families can be achieved while still maintaining alliances with family members.

Jenna, a 16-year-old junior in high school, had just gotten her driver’s license. She realized that she was lucky to have been given a brand new car at 16, because many of her friends did not yet have cars, she was upset that her parents disapproved of her agreement to drive all of her friends to places that she did not even want to go. Jenna was an attractive and well-liked adolescent who had always been an “A” and “B” student, and she and her family had never had conflicts about school. She played the flute in the school’s orchestra, and was not involved in any team sports. Jenna started “going out” with a boy in her grade at school, Brett, who was also 16 years old, shortly after she got her license, and even though they didn’t know each other that well, she felt that they had a close relationship. Since he did not yet have a car, she was the “identified driver” whenever they went out or to parties. Jenna was glad about this, because she didn’t really like alcohol and was relieved that Brett would not be driving, given that he like to drink quite a bit at parties. Jenna got along fairly well with her parents, who were considered very “easy-going” by her friends, and she felt that she and her parents had similar values and ideas.

Things were going well until Brett began to pressure her to go further in their sexual relationship. When Jenna told him that she wasn’t ready, Brett hounded her more. When the subject of sex had come up with her parents “hypothetically” in the
past, they had dismissed the subject, indicating that when it was the right time for her, Jenna would know. Jenna knew that she was not ready to have sex, although many of her classmates were sexually active. Jenna was not an impulsive person and liked to plan things carefully so that they would feel right to her. Jenna realized that she could not agree with Brett’s request but she was confident that she could make him understand. One of Jenna’s friends suggested that Brett might break up with her if she didn’t have sex with him, but Jenna was willing to take that risk. Jenna carefully told Brett that she loved him but she was not yet ready for sex. Jenna was slightly surprised that instead of pressuring her more, or breaking up with her, Brett accepted her decision, in fact, he seemed a little relieved.

Jenna and Brett continued their relationship into their senior year of high school, and, toward the end of her senior year, Jenna desired to be sexually active with him. They decided to go to a community clinic known for its positive attitude toward adolescents, to learn about birth control methods and pick one, without the including their parents. Jenna and Brett took the time to learn about a variety of birth control methods and chose to use condoms. When they left the clinic, Jenna and Brett felt closer than they had before, and realized how they had both grown in their relationship. Jenna and Brett both felt that they were doing the right thing. (Courtesy of Caroly S. Pataki, M.D.).

Late Adolescence. Late adolescence (between the ages of 17 and 19) is a time when continued exploration of academic pursuits, musical and artistic tastes, athletic participation, and social bonds lead a teen toward greater definition of self and a sense of belonging to certain groups or subcultures within mainstream society. Well-adjusted adolescents can be comfortable with current choices of activities, tastes, hobbies, and friendships, yet remain aware that their “identities” will continue to be refined during young adulthood.

Joey was in his second semester of his freshman year of college, living away from home, and had just turned 18 years of age. He reflected on the fact that he was no longer a “minor” and could make almost any decision for himself without his parents being involved.

Joey felt liberated, but at the same time, he was confused and a little lost. Since 10th grade, Joey had planned to pursue a career in medicine like his father, so he had taken a heavy load of science courses in the first semester, all of which he had despised. This semester, however, he had signed up only for liberal arts classes. He did not mention this to his father. He was now enrolled in classes that ranged from art history to architectural drafting to sociology, philosophy, and music. He had been influenced, he believed, by his roommate Tony, who was in the architecture program, and by his girlfriend, Lisa, who was majoring in studio art.

As the semester progressed, Joey found that his favorite course was the drafting
class, just like Tony had predicted. Tony was in a more advanced drafting class than Joey, and Joey couldn't help but wonder whether he liked the drafting class so much because of how much he idolized Tony, or because he really enjoyed the class. He talked this over with Lisa, who suggested that he chill out and not figure out the rest of his life right now. She recommended that he take at least two more semesters of varied classes including those in the architecture curriculum before making a final decision about a career. Joey realized that Lisa’s approach to college, and to life was so relaxed, the opposite of his approach, following his parents’ pressure to plan ahead, make commitments early, and see them through, regardless of how it felt. Lisa’s approach left more room for reflecting on experiences, and then making a choice, rather than jumping into what he was “supposed” to do. Joey took her advice and allowed himself another year to try out majors and then decide on a career. After experiencing courses in many varied subjects, Joey decided that he did truly enjoy architecture and was able to switch his focus from premed to architecture. (Courtesy of Caroly S. Pataki M.D.)

Components of Adolescence

**Physical Development.** Puberty is the process by which adolescents develop physical and sexual maturity, along with reproductive ability. The first signs of the pubertal process are an increased rate of growth in both height and weight. This process begins in girls by approximately 10 years of age. By the age of 11 or 12, many girls noticeably tower over their male classmates, who do not experience a growth spurt, on average, until they reach 13 years of age. By age 13, many girls have experienced menarche, and most have developed breasts and pubic hair.

Wide variation exists in the normal range of onset and timing of pubertal development and its components. A set sequence occurs, however, in the order in which pubertal development proceeds. Thus, secondary sexual characteristics in boys, such as increased length and width of the penis, for example, will occur after the release of androgens from developed enlarged testes.

Sexual maturity ratings (SMR), also referred to as Tanner Stages, range from SMR 1 (prepuberty) to SMR 5 (adult). The SMR ratings include stages of genital maturity in boys and breast development in girls, as well as pubic hair development. Table 31.1-11 outlines sexual maturity ratings for boys and girls.

<table>
<thead>
<tr>
<th>Table 31.1-11</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sexual Maturity Ratings for Male and Female Adolescents</td>
</tr>
</tbody>
</table>
The primary female sex characteristic is ovulation, the release of eggs from ovarian follicles, approximately once every 28 days. When adolescent girls reach SMR 3 to 4, ovarian follicles are producing enough estrogen to result in menarche, the onset of menstruation. When adolescent girls reach SMR 4 to 5, an ovarian follicle matures on a monthly basis and ovulation occurs. Estrogen and progesterone promote sexual maturation, including further development of fallopian tubes and breasts.

For adolescent boys, the primary sex characteristic is the development of sperm by the testes. In boys, sperm development occurs in response to follicle-stimulating hormone acting on the seminiferous tubules within the testes. The pubertal process in boys is marked by the growth of the testes stimulated by luteinizing hormone. An adolescent boy’s ability to ejaculate generally emerges within 1 year of reaching SMR 2. Secondary sexual characteristics in boys include thickening of skin, broadening of the shoulders, and the development of facial hair.

Cognitive Maturation. Cognitive maturation in adolescence encompasses a wide range of expanded abilities that fall within the global category of executive functions of the brain. These include the transition from concrete thinking to more abstract thinking; an increased ability to draw logical conclusions in scientific pursuits, with peer interactions and in social situations; and new abilities for self-observation and self-regulation. Adolescents acquire increased awareness of their own intellectual, artistic, and athletic gifts and talents; yet it often takes many more years into young adulthood to establish a practical application for these abilities.

The central cognitive change that occurs gradually during adolescence is the shift from concrete thinking (concrete operational thinking, according to Jean Piaget) to the ability to think abstractly (formal operational thinking, in Piaget’s terminology). This evolution occurs as an adaptation to stimuli that demand an adolescent to produce hypothetical responses, as well as in response to the adolescent’s expanded abilities to provide generalizations from specific situations. The development of abstract thinking is not a sudden epiphany but, rather, a gradual process of expanding logical deductions beyond concrete experiences and achieving the capacity for idealistic and hypothetical
Adolescents often use an omnipotent belief system that reinforces their sense of immunity from danger, even when confronted with logical risks. Some degree of child-like magical thinking continues to coexist with more mature abstract thinking in many adolescents. Despite the persistence of magical thinking into adolescence, adolescent cognition departs from that of younger children insofar as the increased ability for self-observation and development of strategies to promote strengths and compensate for weaknesses.

One of the important cognitive tasks in adolescence is to identify and gravitate toward those pursuits that seem to match the adolescent’s cognitive strengths, in academic courses and in thinking about future aspirations. Piaget believed that cognitive adaptation in adolescence is profoundly influenced by social relationships and the dialogue between adolescents and peers, making social cognition an integral part of cognitive development in adolescence.

Socialization. Socialization in adolescence encompasses the ability to find acceptance in peer relationships, as well as the development of more mature social cognition. The skills to develop a sense of belonging to a peer group are of central importance to a sense of well-being. Being viewed as socially competent by peers is a critical component in building good self-esteem for most early adolescents. Peer influences are powerful and can foster positive social interactions, as well as apply pressure in less socially accepted behaviors or even high-risk behavior. Belonging to a peer group is, in general, a sign of adaptation and a developmentally appropriate step in separating from parents and turning the focus of loyalty toward friends. Children between the ages of 6 and 12 are able to engage in exchanges of ideas and opinions and acknowledge feelings of peers, but the relationships often wax and wane in a discontinuous way on the basis of altercations and good times. Friendships deepen with repeated good times but, for some school-aged children, a variety of peers are often interchangeable—that is, a companion is sought when a given child has free time, rather than out of a desire to spend time with a specific friend. As adolescence ensues, friendships become more individualized, and personal secrets are likely shared with a friend rather than a family member. A comfort level is achieved with one or several early adolescent peers, and the group may “stick together,” spending most free time together. In early adolescence, a blend of the above two social modes may emerge, small “cliques” arise, and, even within the cliques, competition and jealousies regarding which dyads are “preferred” or higher ranked within the clique may result in some discontinuities in the relationships. In later adolescence, the peer group solidifies, leading to increased stability in the friendships and a greater mutuality in the quality of the interactions.

Moral Development. Morality is a set of values and beliefs about codes of behavior that conform to those shared by others in society. Adolescents, as do younger children, tend to develop patterns of behaviors characteristic of their family and
Piaget described moral development as a gradual process parallel to cognitive development, with expanded abilities in differentiating the best interests for society from those of individuals occurring during late adolescence. Preschool children simply follow rules set forth by the parents; in the middle years, children accept rules but show an inability to allow for exceptions; and during adolescence, young persons recognize rules in terms of what is good for the society at large.

Lawrence Kohlberg integrated Piaget’s concepts and described three major levels of morality. The first level is preconventional morality, in which punishment and obedience to the parent are the determining factors. The second level is morality of conventional role-conformity, in which children try to conform to gain approval and to maintain good relationships with others. The third and highest level is morality of self-accepted moral principles, in which children voluntarily comply with rules on the basis of a concept of ethical principles and make exceptions to rules in certain circumstances.

Although Kohlberg’s and Piaget’s notions of moral development focus on a unified theory of cognitive maturation for both sexes, Carol Gilligan emphasizes the social context of moral development leading to divergent patterns in moral development. Gilligan points out that, in women, compassion and the ethics of caring are dominant features of moral decision-making, whereas, for men, predominant features of moral judgments are related more to a perception of justice, rationality, and a sense of fairness.

**Self-Esteem.** Self-esteem is a measure of one’s sense of self-worth based on perceived success and achievements, as well as a perception of how much one is valued by peers, family members, teachers, and society in general. The most important correlates of good self-esteem are one’s perception of positive physical appearance and high value to peers and family. Secondary features of self-esteem relate to academic achievement, athletic abilities, and special talents. Adolescent self-esteem is mediated, to a significant degree, by positive feedback received from a peer group and family members, and adolescents often seek out a peer group that offers acceptance, regardless of negative behaviors associated with that group. Adolescent girls have more of a problem maintaining self-esteem than do boys. Girls continued to rate themselves with generally lower self-esteem into adulthood.

**Current Environmental Influences and Adolescence**

**Adolescent Sexual Behavior.** Sexual experimentation in adolescents often begins with fantasy and masturbation in early adolescence followed by noncoital genital touching with the opposite sex or, in some cases, same-sex partners, oral sex with partners, and initiation of sexual intercourse at a later point in development. By high school, most male adolescents report experience with masturbation, and more than half
of adolescent girls report masturbation. The balance between healthy adolescent sexual experimentation and emotionally and physically safe sexual practices is one of the major challenges for society.

Estimates vary, but about 50 percent of 9th to 12th grade students reported having had sexual intercourse. The median age at first intercourse is about 16 years for boys and 17 years for girls. Boys generally have more sexual partners than do girls, and boys are less likely than girls to seek emotional attachments with their sexual partners.

FACTORS INFLUENCING ADOLESCENT SEXUAL BEHAVIOR. Factors that affect sexual behavior in adolescents include personality traits, gender, cultural and religious background, racial factors, family attitudes, and sexual education and prevention programs.

Personality factors have been found to be associated with sexual behavior, as well as sexual risk-taking. Higher levels of impulsivity are associated with a younger age at first experience of sexual intercourse; higher number of sexual partners; sexual intercourse without the use of contraception, including condoms; and a history of sexually transmitted disease (chlamydia).

Historically, male adolescents have initiated sexual intercourse at a younger age than female adolescents. The younger a teenage girl is when she has sex for the first time, the more likely she is to have had unwanted sexual activity. Close to four of ten girls who had first intercourse at 13 or 14 years of age report it was either not voluntary or unwanted. Three of four girls and over half of boys report that girls who have sex do so because their boyfriends want them to. In general, adolescents who initiate sexual intercourse at younger ages are also more likely to have a greater number of sexual partners.

The additive effects of more highly educated families, social and religious youth groups, and school-based educational programs can be credited with a decline in high-risk sexual behavior among adolescents. Responsible sexual behavior among adolescents has been determined as one of the ten leading health indicators for the next decade. The primary reason that teenage girls who have never had intercourse give for abstaining from sex is that having sex would be against their religious or moral values. Other reasons include desire to avoid pregnancy, fear of contracting a sexually transmitted disease (STD), and not having met the appropriate partner.

CONTRACEPTIVES. Currently, 98 percent of teenagers 15 to 19 years are using at least one method of birth control. The two most common methods are condoms and birth control pills. STDs, despite use of condoms, are still at high levels in teens. Approximately one in four sexually active teens contracts an STD every year. Approximately half of all new human immunodeficiency virus (HIV) infections occur in people younger than age 25.

PREGNANCY. Each year 750,000 to 850,000 teenage girls younger than age 19 become pregnant. Of this number, 432,000 give birth, a 19 percent decline from 532,000 in 1991; the rest (418,000) obtain abortions. The largest decline in teen pregnancy by race is for black women. Hispanic teen births have declined 20 percent, but continue to have the highest teen birth rates compared with other races.
Teenage pregnancy creates a plethora of health risks for both mother and child. Children born to teenage mothers have a greater chance of dying before the age of 5 years. Those who survive are more likely to perform poorly in school and are at greater risk of abuse and neglect. Teenage mothers are less likely to gain adequate weight during pregnancy, increasing the risk of premature births and low-birth-weight infants. Low-birth-weight babies are more likely to have organs that are not fully developed, resulting in bleeding in the brain, respiratory distress syndrome, and intestinal problems. Teenage mothers are also less likely to seek regular prenatal care and to take recommended daily multivitamins, and they are more likely to smoke, drink, or use drugs during pregnancy. Only one third of teenage mothers obtain high school diplomas, and only 1.5 percent have a college degree by the age of 30.

The average adolescent mother who cannot care for her child has the child either placed in foster care or raised by the teenager’s already overburdened parents or other relatives. Few teenage mothers marry the fathers of their children; the fathers, usually teenagers, cannot care for themselves, much less the mothers of their children. If the two do marry, they usually divorce. Many are more likely to end up on welfare.

**ABORTION.** Nearly four of ten teen pregnancies end in abortion. Almost all the girls are unwed mothers from low socioeconomic groups; their pregnancies result from sex with boys to whom they felt emotionally attached. Most (61 percent) teenagers elect to have abortions with their parents’ consent, but laws of mandatory parental consent put two rights into competition: a girl’s claim to privacy and a parent’s need to know. Most adults believe that teenagers should have parental permission for an abortion; but when parents refuse to give their consent, most states prohibit parents from vetoing the teenager’s decision.

The abortion rate in many European countries tends to be far lower than that in the United States. In the United States, the rate of abortion among girls between the ages of 15 and 19 is about 30 per 1,000 girls, according to the Centers for Disease Control and Prevention. In France, for instance, about 10.5 of every 1,000 girls under the age of 20 had an abortion, according to World Health Organization statistics. The rate of abortion in Germany was 6.8; in Italy, 6.3; and in Spain, 4.5. Britain has a higher rate, 18.5. Family planning experts believe that more sex education and availability of contraceptive devices help keep the number of abortions down. In Holland, where contraceptives are freely available in schools, the teenage pregnancy rate is among the lowest in the world.

**Risk-Taking Behavior.** Reasonable risk-taking is a necessary endeavor in adolescence, leading to confidence both in forming new relationships and in sports and social situations. High-risk behaviors among adolescents are associated with serious negative consequences, however, and can take many forms, including drug and alcohol use, unsafe sexual practices, self-injurious behaviors, and reckless driving.

**Drug Use**
ALCOHOL. About 30 percent of 12th graders report having five or more drinks in a row within a 2-week period. The average age when youths first try alcohol is 11 years for boys and 13 years for girls. The national average age at which Americans begin drinking regularly is 15.9 years of age. People ages 18 to 25 show the highest prevalence of binge and heavy drinking. Drunk driving has declined since 2002. Alcohol dependence, along with other drugs, is associated with depression, anxiety, oppositional defiant disorder, antisocial personality disorder, and an increased rate of suicide.

NICOTINE. The number of younger Americans who smoke has declined since 1990; however, the rate of smoking among teenagers is still as high as or higher than that of adults. According to the American Cancer Society, on average more than one of five students has smoked cigarettes. Each day, more than 4,000 teenagers try their first cigarette and another 2,000 become regular, daily smokers. Cigarette smokers are more likely to get into fights, carry weapons, attempt suicide, suffer from mental health problems such as depression, and engage in high-risk sexual behaviors. One of three will eventually die from smoking-related diseases. Cigarettes are the most common type of tobacco used among middle-school students followed by cigars, smokeless tobacco, and pipes.

CANNABIS. Marijuana is the most popular illicit drug, with 14.6 million people using it (6.2 percent of the population), two thirds being under the age of 18. Its use, however, is slowly declining. About 6 percent of 12th graders report daily use of marijuana. One of the major reasons for such prevalence of marijuana use among teenagers is because many find that marijuana is easier to get than alcohol or cigarettes. This belief has declined in recent years. Once teenagers are dependent on marijuana, they often tumble into truancy, crime, and depression.

COCAINE. About 13 percent of high school seniors use cocaine, exceeding the national average of 3.6 percent. In addition, about 1 percent of 12th graders admit to using phencyclidine (PCP). Crystal methamphetamine (ice) has an annual prevalence in 12th graders of about 2 percent.

OPIOIDS. In recent years, the number of teens using prescription pain relievers for nonmedical reasons has increased. Prescription drug abuse by people ages 18 to 25 has increased 15 percent. Drugs of specific concern are the pain relievers oxycodone (OxyContin) and hydrocodone (Vicodin). OxyContin has gained ground among high school students since its emergence in 2001, with 5 percent of 12th graders, 3.5 percent of 10th graders, and 1.7 percent of 8th graders reporting use. Vicodin was used by 9.3 percent of 12th graders, 6.2 percent of 10th graders, and 2.5 percent of 8th graders.

HEROIN. Heroin use is prevalent among adolescents, although less so than cocaine. The average age of use is 19, but it is used by almost 2 percent of 12th graders, the nasal route (snorting) being the most common method of use.
Violence. Although rates of violent crime have decreased throughout the United States in recent years, violent crimes by young offenders are on the increase. Homicides are the second leading cause of death among persons ages 15 to 25. (Accidents are first; suicides are third.) Black male teenagers are far more likely to be murder victims than are boys from any other racial or ethnic group or girls of any race. The factor most strongly associated with violence among adolescent boys is growing up in a household without a father or father surrogate; this factor aside, race, socioeconomic status, and education show no effect on the propensity toward violence.

BULLYING. Bullying is defined as the use of one’s strength or status to intimidate, injure, or humiliate another person of lesser strength or status. It can be categorized as physical, verbal, or social. Physical bullying involves physical injury or threat of injury to someone. Verbal bullying refers to teasing or insulting someone. Social bullying refers to the use of peer rejection or exclusion to humiliate or isolate a victim.

Approximately 30 percent of 6th through 10th grade students are involved in some aspect of moderate-to-frequent bullying, either as a bully, the target of bullying, or both. Approximately 1.7 million children within this age group can be identified as bullies. Boys are more likely to be involved in bullying and violent behavior than girls. Girls tend to use verbal bullying rather than physical.

An estimated 160,000 students miss school each day because of fear of attack or intimidation from peers; some are forced to drop out. Stresses of “victimization” can interfere with student’s engagement and learning in school. Children who bully other children are at risk for engaging in more serious violent behaviors, such as frequent fighting and carrying a weapon.

Cyber Bullying. During the last decade, electronic or internet bullying has become of great concern to adolescents. Cyber bullying is defined broadly, to convey the use of electronic means to intentionally intimidate or harm someone. The reported prevalence of cyber bullying is variable, reports ranging from 1% to 62% of youth reporting that they were victims of cyber victimization. A study of about 700 Australian students, recruited at age 10 years, and followed until age 14 to 15 years, found that 15% had engaged in cyber bullying, 21% had engaged in traditional bullying, and 7% had engaged in both. Another study of self-reported information collected from 399 teens in the 8th to 10th grades, found that involvement in cyber bullying, either as a victim or a bully, specifically contributed to the prediction of depressive symptoms and suicidal ideation. This correlation of cyber bullying and depressive symptomatology was found to be stronger than the association of traditional bulling and affective disorder.

Gangs. Gang violence is a problem in various communities throughout the United States. There are 2,000 different youth gangs around the country with more than 200,000 teens and young adults as members. Most members are between the ages of 12 and 24 years, with an average of 17 to 18 years. Gang membership is a brief phase for many teenagers; one half to two thirds leave the gang by the 1-year mark. Boys are
more likely to join gangs than girls; however, female gang membership may be underrepresented. Female gang members are more likely to be found in small cities and rural areas and tend to be younger than male gang members. Female gang members are also involved in less delinquent or criminal activity than males and commit fewer violent crimes.

WEAPONS. Each day, on average, nearly ten American children younger than the age of 18 years are killed in handgun suicides, homicides, and accidents. Many more are wounded. One in five youths in grades 9 to 12 carries a weapon: knife, gun, or club.

By law, firearms cannot be sold to anyone younger than the age of 18 years. Two thirds of students in grades 6 to 12 say that they can get a firearm within 24 hours, however. More than 22 million children live in a home with a firearm. In 40 percent of these homes, at least one gun is kept unlocked and 13 percent are kept unlocked and loaded. Two of three students involved in school shootings acquired their guns from their own home or that of a relative. At least 60 percent of suicide deaths in teens involve the use of a handgun.

SCHOOL VIOLENCE. According to the CDC of all youth homicides in 2010 about 2 percent occurred in schools. Approximately 7 percent of teachers report they have been threatened with injury or physically attacked by a student from their school. In addition, among students in grades 9 through 12, about 6 percent reported carrying a weapon on school property on one or more days in the 30 days before the survey.

Many factors can lead to violent acts in teenagers. Some inherited traits include impulsivity, learning difficulties, low IQ, or fearlessness. A correlation also exists between witnessing violent acts and involvement in violence. Children who witness violent acts are more aggressive and grow up more likely to become involved in violence.either as a victimizer or as a victim. Table 31.1-12 lists some of the early and imminent warning signs of school violence.

Table 31.1-12
Warning Signs of School Violence
On April 20, 1999, two teenage boys, ages 17 and 18 years, went on a shooting rampage through Columbine High School of Littleton, Colorado. Armed with shotguns, a semiautomatic rifle, and a pistol, they laughed and hollered as they shot classmates and teachers at point-blank range while hurling homemade explosives. Fifteen were killed, including the two gunmen, and 25 were injured.

The gunmen were members of the “trench coat mafia” at the high school, a clique of social misfits who stood out at the school for their gothic style of dress and nihilistic attitude. The two gunmen were obsessed with violent video games and intrigued with Nazi culture, even though one was part Jewish. The date of the attack was picked because it was Adolf Hitler’s birthday.

On March 21, 2005, a 16-year-old boy went on a shooting rampage at Red Lake High School on the Red Lake Indian Reservation in far northern Minnesota. He began his shooting spree by killing his grandfather and the grandfather’s companion. He then donned his grandfather’s police-issue gun belt and bulletproof vest before heading to the school, where he killed a security guard, a teacher, five students, and then himself. About 15 others were injured.

The gunman had a troubled childhood; his father committed suicide in 1997 and his mother suffered head injuries in an auto accident. He expressed admiration for Adolf Hitler on a neo-Nazi website, using the handle “Todesengel,” which is German for “Angel of Death.” He had bouts of depression, suicide ideation, and was taking fluoxetine (Prozac). He was a member of a clique of about five students known as “The Darkers,” who wore black clothes and chains, spiked or dyed their hair, and loved heavy-metal music. The gunman was usually seen in a long black trench coat, eyeliner, and combat boots, and was described as a quiet teenager.

Adolescents younger than age 18 years account for 20 percent of arrests for all sexual offenses (excluding prostitution), 20 to 30 percent of rape cases, 14 percent of aggravated sexual assault offenses, and 27 percent of child sexual homicides. These adolescent offenders account for the victimization of approximately one half of boys and one fourth of girls who are molested or sexually abused. Most instances have involved adolescent male perpetrators.

There appear to be two types of juvenile sex offenders: those who target children and those who offend against peers or adults. The main distinction between the two groups is based on the age difference between the victim and the offender. Table 31.1-13 lists the differences and similarities of these two groups.

| **Juvenile Offenders Who Sexually Offend against Children** | Most victims are male and are related to them, either siblings or other relatives. |
| | Almost half of the offenders have had at least one male victim. |
| | The sexual crimes tend to reflect a greater reliance on opportunity and guile than injurious force. This appears to be particularly true when their victim is related to them. These youths may "trick" the child into complying with the molestation, use bribes, or threaten the child with loss of the relationship. |
| | Within the overall population of juveniles who sexually assault children are certain youths who display high levels of aggression and violence. Generally, these are youths who display more severe levels of personality and/or psychosexual disturbances, such as psychopathy, sexual sadism, and so on. |
| | Suffer from deficits in self-esteem and social competency |
| | Many show evidence of depression. |
| **Characteristics Common to Both Groups** | High rates of learning disabilities and academic dysfunction (30 to 60 percent) |
| | The presence of other behavioral health problems, including substance abuse, and disorders of conduct (up to 80 percent have some diagnosable psychiatric disorder) |
| | Observed difficulties with impulse control and judgment |

Etiological factors of juvenile sex offending include maltreatment experiences, exposure to pornography, substance abuse, and exposure to aggressive role models. A significant number of offending adolescents have a childhood history of physical abuse (25 to 50 percent) or sexual abuse (10 to 80 percent). Half of adolescent offenders lived with both parents and one other juvenile at the time of their offending. Evidence also
suggests that most juvenile sex offenders are likely to become adult sex offenders. The most common psychosocial deficits of adolescent sexual offenders include low self-esteem, few social skills, minimal assertive skills, and poor academic performance. The most common psychiatric diagnoses are conduct disorder, substance abuse disorder, adjustment disorder, attention-deficit/hyperactivity disorder, specific phobia, and mood disorders. Male offenders are more often diagnosed with paraphilias and antisocial behavior, whereas female offenders are more likely to be diagnosed with mood disorders and engage in self-mutilation.

**Prostitution.** Teenagers constitute a large portion of all prostitutes, with estimates ranging up to 1 million teenagers involved in prostitution. The average age of a new recruit is 13 years; however, some are as young as 9 years of age. Most adolescent prostitutes are girls, but boys are involved as homosexual prostitutes. Most teenagers who enter a life of prostitution come from broken homes; however, a growing number of teenage prostitutes come from middle- to upper middle-class homes. Many have been victims of rape, or were abused as children. Most teenagers ran away from home and were taken in by pimps and substance abusers; the adolescents themselves then became substance abusers. Twenty-seven percent of teenage prostitution occurs in large cities, and incidents usually take place at an outside location, such as highways, roads, alleys, fields, woods, or parking lots. Teenage prostitutes are at high risk for acquired immunodeficiency syndrome (AIDS), and many (up to 70 percent in some studies) are infected with HIV.

As many as 17,500 individuals are smuggled into the United States each year as “sex slaves.” They are brought under the pretenses of a better life and job opportunities, but once they are in the United States, they are forced into prostitution, making little money while traffickers make thousands of dollars from their services. Many times they are raped and abused.

**Tattoos and Body Piercing.** Body piercing and tattoos have become more prevalent among adolescents since the 1980s. In the general population, approximately 10 to 13 percent of adolescents have tattoos. Of the more than 500 adolescents surveyed in a study, 13.2 percent report at least one tattoo, and 26.9 percent report at least one body piercing, other than in their ear lobe, at some point in their lives. Both tattoos and body piercing are more common in girls than in boys. Adolescents who endorsed possession of at least one tattoo or body piercing are more likely to endorse use of gateway drugs (cigarettes, alcohol, marijuana), as well as experience with hard drugs (cocaine, crystal methamphetamine, and ecstasy).

Bonanno RA, Hymel S. Cyber bullying and internalizing difficulties: Above and beyond the impact of traditional forms of
A comprehensive evaluation of a child is composed of interviews with the parents, the child, and other family members; gathering information regarding the child's current school functioning; and often, a standardized assessment of the child's intellectual level and academic achievement. In some cases, standardized measures of developmental level and neuropsychological assessments are useful. Psychiatric evaluations of children are rarely initiated by the child, so clinicians must obtain information from the family and the school to understand the reasons for the evaluation. In some cases, the court or a child protective service agency may initiate a psychiatric evaluation. Children can be...
excellent informants about symptoms related to mood and inner experiences, such as psychotic phenomena, sadness, fears, and anxiety, but they often have difficulty with the chronology of symptoms and are sometimes reticent about reporting behaviors that have gotten them into trouble. Very young children often cannot articulate their experiences verbally and do better showing their feelings and preoccupations in a play situation. Assessment of a child or adolescent includes identifying the reasons for referral; assessing the nature and extent of the child’s psychological and behavioral difficulties; and determining family, school, social, and developmental factors that may be influencing the child’s emotional well-being.

The first step in the comprehensive evaluation of a child or adolescent is to obtain a full description of the current concerns and a history of the child’s previous psychiatric and medical problems. This is often done with the parents for school-aged children, whereas adolescents may be seen alone first, to get their perception of the situation. Direct interview and observation of the child is usually next, followed by psychological testing, when indicated.

Clinical interviews offer the most flexibility in understanding the evolution of problems and in establishing the role of environmental factors and life events, but they may not systematically cover all psychiatric diagnostic categories. To increase the breadth of information generated, the clinician may use semistructured interviews such as the Kiddie Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS); structured interviews such as the National Institute for Mental Health Diagnostic Interview Schedule for Children Version IV (NIMH DISC-IV); and rating scales, such as the Child Behavior Checklist and Connors Parent or Teacher Rating Scale for ADHD.

It is not uncommon for interviews from different sources, such as parents, teachers, and school counselors, to reflect different or even contradictory information about a given child. When faced with conflicting information, the clinician must determine whether apparent contradictions actually reflect an accurate picture of the child in different settings. Once a complete history is obtained from the parents, the child is examined, the child’s current functioning at home and at school is assessed, and psychological testing is completed, the clinician can use all the available information to make a best-estimate diagnosis and can then make recommendations.

Once clinical information is obtained about a given child or adolescent, it is the clinician’s task to determine whether criteria are met for one or more psychiatric disorders according to the Fifth Edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5). This most current version is a categorical classification reflecting the consensus on constellations of symptoms believed to comprise discrete and valid psychiatric disorders. Psychiatric disorders are defined by the DSM-5 as a clinically significant set of symptoms that is associated with impairment in one or more areas of functioning. Whereas clinical situations requiring intervention do not always fall within the context of a given psychiatric disorder, the importance of identifying psychiatric disorders when they arise is to facilitate meaningful investigation of childhood psychopathology.
To conduct a useful interview with a child of any age, clinicians must be familiar with normal development to place the child’s responses in the proper perspective. For example, a young child’s discomfort on separation from a parent and a school-age child’s lack of clarity about the purpose of the interview are both perfectly normal and should not be misconstrued as psychiatric symptoms. Furthermore, behavior that is normal in a child at one age, such as temper tantrums in a 2-year-old, takes on a different meaning, for example, in a 17-year-old.

The interviewer’s first task is to engage the child and develop a rapport so that the child is comfortable. The interviewer should inquire about the child’s concept of the purpose of the interview and should ask what the parents have told the child. If the child appears to be confused about the reason for the interview, the examiner may opt to summarize the parents’ concerns in a developmentally appropriate and supportive manner. During the interview with the child, the clinician seeks to learn about the child’s relationships with family members and peers, academic achievement and peer relationships in school, and the child’s pleasurable activities. An estimate of the child’s cognitive functioning is a part of the mental status examination.

The extent of confidentiality in child assessment is correlated with the age of the child. In most cases, almost all specific information can appropriately be shared with the parents of a very young child, whereas privacy and permission of an older child or adolescent are mandated before sharing information with parents. School-age and older children are informed that if the clinician becomes concerned that any child is dangerous to himself or herself or to others, this information must be shared with parents and, at times, additional adults. As part of a psychiatric assessment of a child of any age, the clinician must determine whether that child is safe in his or her environment and must develop an index of suspicion about whether the child is a victim of abuse or neglect. Whenever there is a suspicion of child maltreatment, the local child protective service agency must be notified.

Toward the end of the interview, the child may be asked in an open-ended manner whether he or she would like to bring up anything else. Each child should be complimented for his or her cooperation and thanked for participating in the interview, and the interview should end on a positive note.

**Infants and Young Children**

Assessments of infants usually begin with the parents present, because very young children may be frightened by the interview situation; the interview with the parents present also allows the clinician to assess the parent–infant interaction. Infants may be referred for a variety of reasons, including high levels of irritability, difficulty being consoled, eating disturbances, poor weight gain, sleep disturbances, withdrawn behavior, lack of engagement in play, and developmental delay. The clinician assesses areas of functioning that include motor development, activity level, verbal
communication, ability to engage in play, problem-solving skills, adaptation to daily routines, relationships, and social responsiveness.

The child’s developmental level of functioning is determined by combining observations made during the interview with standardized developmental measures. Observations of play reveal a child’s developmental level and reflect the child’s emotional state and preoccupations. The examiner can interact with an infant age 18 months or younger in a playful manner by using such games as peek-a-boo. Children between the ages of 18 months and 3 years can be observed in a playroom. Children ages 2 years or older may exhibit symbolic play with toys, revealing more in this mode than through conversation. The use of puppets and dolls with children younger than 6 years of age is often an effective way to elicit information, especially if questions are directed to the dolls, rather than to the child.

School-Age Children

Some school-age children are at ease when conversing with an adult; others are hampered by fear, anxiety, poor verbal skills, or oppositional behavior. School-age children can usually tolerate a 45-minute session. The room should be sufficiently spacious for the child to move around, but not so large as to reduce intimate contact between the examiner and the child. Part of the interview can be reserved for unstructured play, and various toys can be made available to capture the child’s interest and to elicit themes and feelings. Children in lower grades may be more interested in the toys in the room, whereas by the sixth grade, children may be more comfortable with the interview process and less likely to show spontaneous play.

The initial part of the interview explores the child’s understanding of the reasons for the meeting. The clinician should confirm that the interview was not set up because the child is “in trouble” or as a punishment for “bad” behavior. Techniques that can facilitate disclosure of feelings include asking the child to draw peers, family members, a house, or anything else that comes to mind. The child can then be questioned about the drawings. Children may be asked to reveal three wishes, to describe the best and worst events of their lives, and to name a favorite person to be stranded with on a desert island. Games such as Donald W. Winnicott’s “squiggle,” in which the examiner draws a curved line and then the child and the examiner take turns continuing the drawing, may facilitate conversation.

Questions that are partially open-ended with some multiple choices may elicit the most complete answers from school-age children. Simple, closed (yes or no) questions may not elicit sufficient information, and completely open-ended questions can overwhelm a school-age child who cannot construct a chronological narrative. These techniques often result in a shoulder shrug from the child. The use of indirect commentary—such as, “I once knew a child who felt very sad when he moved away from all his friends”—is helpful, although the clinician must be careful not to lead the child into confirming what the child thinks the clinician wants to hear. School-age children respond well to clinicians who help them compare moods or feelings by asking
them to rate feelings on a scale of 1 to 10.

**Adolescents**

Adolescents usually have distinct ideas about why the evaluation was initiated, and can usually give a chronological account of the recent events leading to the evaluation, although some may disagree with the need for the evaluation. The clinician should clearly communicate the value of hearing the story from an adolescent’s point of view and must be careful to reserve judgment and not assign blame. Adolescents may be concerned about confidentiality, and clinicians can assure them that permission will be requested from them before any specific information is shared with parents, except in situations involving danger to the adolescent or others, in which case confidentiality must be sacrificed. Adolescents can be approached in an open-ended manner; however, when silences occur during the interview, the clinician should attempt to reengage the patient. Clinicians can explore what the adolescent believes the outcome of the evaluation will be (change of school, hospitalization, removal from home, removal of privileges).

Some adolescents approach the interview with apprehension or hostility, but open up when it becomes evident that the clinician is neither punitive nor judgmental. Clinicians must be aware of their own responses to adolescents’ behavior (countertransference) and stay focused on the therapeutic process even in the face of defiant, angry, or difficult teenagers. Clinicians should set appropriate limits and should postpone or discontinue an interview if they feel threatened or if patients become destructive to property or engage in self-injurious behavior. Every interview should include an exploration of suicidal thoughts, assaultive behavior, psychotic symptoms, substance use, and knowledge of safe sexual practices along with a sexual history. Once rapport has been established, many adolescents appreciate the opportunity to tell their side of the story and may reveal things that they have not disclosed to anyone else.

**Family Interview**

An interview with parents and the patient may take place first or may occur later in the evaluation. Sometimes, an interview with the entire family, including siblings, can be enlightening. The purpose is to observe the attitudes and behavior of the parents toward the patient and the responses of the children to their parents. The clinician’s job is to maintain a nonthreatening atmosphere in which each member of the family can speak freely without feeling that the clinician is taking sides with any particular member. Although child psychiatrists generally function as advocates for the child, the clinician must validate each family member’s feelings in this setting, because lack of communication often contributes to the patient’s problems.

**Parents**

The interview with the patient’s parents or caretakers is necessary to get a chronological
picture of the child’s growth and development. A thorough developmental history and details of any stressors or important events that have influenced the child’s development must be elicited. The parents’ view of the family dynamics, their marital history, and their own emotional adjustment are also elicited. The family’s psychiatric history and the upbringing of the parents are pertinent. Parents are usually the best informants about the child’s early development and previous psychiatric and medical illnesses. They may be better able to provide an accurate chronology of past evaluations and treatment. In some cases, especially with older children and adolescents, the parents may be unaware of significant current symptoms or social difficulties of the child. Clinicians elicit the parents’ formulation of the causes and nature of their child’s problems and ask about their expectations for the current assessment.

**DIAGNOSTIC INSTRUMENTS**

The two main types of diagnostic instruments used by clinicians are diagnostic interviews and questionnaires. Diagnostic interviews are administered to either children or their parents and typically are designed to elicit sufficient information on various aspects of functioning in order to determine whether DSM-5 criteria are met.

Semistructured interviews, or “interviewer-based” interviews, such as K-SADS and the *Child and Adolescent Psychiatric Assessment* (CAPA), serve as guides for the clinician. They help the clinician clarify answers to questions about symptoms. Structured interviews, or “respondent-based” interviews, such as NIMH DISC-IV, the *Children’s Interview for Psychiatric Syndromes* (ChIPS), and the *Diagnostic Interview for Children and Adolescents* (DICA), provide a script for the interviewer without interpretation of the patient responses during the interview process. Two other diagnostic instruments, the Dominic-R and the *Pictorial Instrument for Children and Adolescents* (PICA-III-R), use pictures as cues along with an accompanying question to elicit information about symptoms, which can be especially useful for young children as well as for adolescents.

Diagnostic instruments aid the collection of information in a systematic way. Diagnostic instruments, even the most comprehensive, however, cannot replace clinical interviews, because clinical interviews are superior in understanding the chronology of symptoms, the interplay between environmental stressors and emotional responses, and developmental issues. Clinicians often find it helpful to combine data from diagnostic instruments with clinical material gathered in a comprehensive evaluation.

Questionnaires can cover a broad range of symptom areas, such as the *Achenbach Child Behavior Checklist*, or they can be focused on a particular type of symptomatology, such as the *Connors Parent Rating Scale for ADHD*.

**Semistructured Diagnostic Interviews**

*Kiddie Schedule for Affective Disorders and Schizophrenia for School-Age Children.* The K-SADS can be used for children and adolescents from 6 to 18 years of age. It contains multiple items with some space for further clarification of
symptoms. It elicits information on current diagnosis and on symptoms present in the
previous year. Another version can also ascertain lifetime diagnoses. This instrument
has been used extensively, especially in evaluation of mood disorders, and includes
measures of impairment caused by symptoms. The schedule comes in a form for parents
to give information about their child and in a version for use directly with the child. The
schedule takes about 1 to 1.5 hours to administer. The interviewer should have some
training in the field of child psychiatry, but need not be a psychiatrist.

**Child and Adolescent Psychiatric Assessment.** The CAPA is an “interviewer-
based” instrument that can be used for children from 9 to 17 years of age. It comes in
modular form so that certain diagnostic entities can be administered without having to
give the entire interview. It covers disruptive behavior disorders, mood disorders,
anxiety disorders, eating disorders, sleep disorders, elimination disorders, substance use
disorders, tic disorders, schizophrenia, posttraumatic stress disorder, and somatization
symptoms. It focuses on the 3 months before the interview, called the “primary period.”
In general, it takes about 1 hour to administer. It has a glossary to help clarify
symptoms, and it provides separate ratings for presence and severity of symptoms. The
CAPA can be used to obtain information that is applicable to making diagnoses
according to the DSM-5. Training is necessary to administer this interview, and the
interviewer must be prepared to use some clinical judgment in interpreting elicited
symptoms.

**Structured Diagnostic Interviews**

**National Institute of Mental Health Interview Schedule for Children**

**Version IV.** The NIMH DISC-IV is a highly structured interview designed to assess
more than 30 DSM-IV diagnostic entities administered by trained “laypersons.” Although
it was formulated to match diagnostic criteria in DSM-IV, information from this
interview can be utilized, along with clinical information for diagnoses in DSM-5. It is
available in parallel child and parent forms. The parent form can be used for children
from 6 to 17 years of age, and the direct child form of the instrument was designed for
children from 9 to 17 years of age. A computer scoring algorithm is available. This
instrument assesses the presence of diagnoses that have been present within the last 4
weeks, and also within the last year. Because it is a fully structured interview, the
instructions serve as a complete guide for the questions, and the examiner need not have
any knowledge of child psychiatry to administer the interview correctly.

**Children’s Interview for Psychiatric Syndromes.** The ChIPS is a highly
structured interview designed for use by trained interviewers with children from 6 to 18
years of age. It is composed of 15 sections, and it elicits information on psychiatric
symptoms as well as psychosocial stressors targeting 20 psychiatric disorders, according
to DSM-IV criteria; however, it can also be applied to diagnoses in DSM-5. There are
parent and child forms. It takes approximately 40 minutes to administer the ChIPS.
Diagnoses covered include depression, mania, attention-deficit/hyperactivity disorder (ADHD), separation disorder, obsessive-compulsive disorder (OCD), conduct disorder, substance use disorder, anorexia, and bulimia. The ChIPS was designed for use as a screening instrument for clinicians and a diagnostic instrument for clinical and epidemiological research.

Diagnostic Interview for Children and Adolescents. The current version of the DICA was developed in 1997 to assess information resulting in diagnoses according to either DSM-IV or DSM-III-R. This instrument can be used to help obtain information that can be applied to DSM-5 as well. Although the DICA was originally designed to be a highly structured interview, it can now be used in a semistructured format. This means that, although interviewers are allowed to use additional questions and probes to clarify elicited information, the method of probing is standardized so that all interviewers will follow a specific pattern. When using the interview with younger children, more flexibility is built in, allowing interviewers to deviate from written questions to ensure that the child understands the question. Parent and child interviews are expected to be used. The DICA is designed for use with children 6 to 17 years of age and generally takes 1 to 2 hours to administer. It covers externalizing behavior disorders, anxiety disorders, depressive disorders, and substance abuse disorders, among others.

Pictorial Diagnostic Instruments

Dominic-R. The Dominic-R is a pictorial, fully structured interview designed to elicit psychiatric symptoms from children 6 to 11 years of age. The pictures illustrate abstract emotional and behavioral content of diagnostic entities according to the DSM-III-R; however, information gleaned from this instrument can also be applied in conjunction with clinical information to the DSM-5. The instrument uses a picture of a child called “Dominic” who is experiencing the symptom in question. Some symptoms have more than one picture, with a brief story that is read to the child. Along with each picture is a sentence asking about the situation being shown and asking the child if he or she has experiences similar to the one that Dominic is having. Diagnostic entities covered by the Dominic-R include separation anxiety, generalized anxiety, depression and dysthymia, ADHD, oppositional defiant disorder, conduct disorder, and specific phobia. Although symptoms of the preceding diagnoses can be fully elicited from the Dominic-R, no specific provision within the instrument inquires about frequency of the symptom, duration, or age of onset. The paper version of this interview takes about 20 minutes, and the computerized version of this instrument takes about 15 minutes. Trained lay-interviewers can administer this interview. Computerized versions of this interview are available with pictures of a child who is white, black, Latino, or Asian.

Pictorial Instrument for Children and Adolescents. PICA-III-R is composed of 137 pictures organized in modules and designed to cover five diagnostic categories, including disorders of anxiety, mood, psychosis, disruptive disorders, and substance use
disorder. It is designed to be administered by clinicians and can be used for children and adolescents ranging from 6 to 16 years of age. The PICA-III_R provides a categorical (diagnosis present or absent) and a dimensional (range of severity) assessment. This instrument presents pictures of a child experiencing emotional, behavioral, and cognitive symptoms. The child is asked, “How much are you like him/her?” and a five-point rating scale with pictures of a person with open arms in increasing degrees is shown to the child to help him or her identify the severity of the symptoms. It takes about 40 minutes to 1 hour to administer the interview. This instrument is currently keyed to the DSM-III-R, but can be used along with clinical information to make diagnoses according to the DSM-5. This assessment can be used to aid in clinical interviews and in research diagnostic protocols.

QUESTIONNAIRES AND RATING SCALES

Achenbach Child Behavior Checklist

The parent and teacher versions of the *Achenbach Child Behavior Checklist* were developed to cover a broad range of symptoms and several positive attributes related to academic and social competence. The checklist presents items related to mood, frustration tolerance, hyperactivity, oppositional behavior, anxiety, and various other behaviors. The parent version consists of 118 items to be rated 0 (not true), 1 (sometimes true), or 2 (very true). The teacher version is similar, but without the items that apply only to home life. Profiles were developed based on normal children of three different age groups (4 to 5, 6 to 11, and 12 to 16).

Such a checklist identifies specific problem areas that might otherwise be overlooked, and it may point out areas in which the child’s behavior deviates from that of normal children of the same age group. The checklist is not used specifically to make diagnoses.

Revised Achenbach Behavior Problem Checklist

Consisting of 150 items that cover a variety of childhood behavioral and emotional symptoms, the *Revised Achenbach Behavior Problem Checklist* discriminates between clinic-referred and nonreferred children. Separate subscales have been found to correlate in the appropriate direction with other measures of intelligence, academic achievement, clinical observations, and peer popularity. As with the other broad rating scales, this instrument can help elicit a comprehensive view of a multitude of behavioral areas, but it is not designed to make psychiatric diagnoses.

Connors Abbreviated Parent-Teacher Rating Scale for ADHD

In its original form, the *Connors Abbreviated Parent-Teacher Rating Scale for ADHD* consisted of 93 items rated on a 0 to 3 scale and was subgrouped into 25 clusters, including problems with restlessness, temper, school, stealing, eating, and sleeping. Over the years, multiple versions of this scale were developed and used to aid in
systematic identification of children with ADHD. A highly abbreviated form of this rating scale, the Connors Abbreviated Parent-Teacher Questionnaire, was developed for use with both parents and teachers by Keith Connors in 1973. It consists of ten items that assess both hyperactivity and inattention.

**Brief Impairment Scale**

A newly validated 23-item instrument suitable to obtain information on children ranging from 4 years to 17 years, the Brief Impairment Scale (BIS) evaluates three domains of functioning: interpersonal relations, school/work functioning, and care/self-fulfillment. This scale is administered to an adult informant about his or her child, does not take long to administer, and provides a global measure of impairment along the above three dimensions. This scale cannot be used to make clinical decisions on individual patients, but it can provide information on the degree of impairment that a given child is experiencing in a certain area.

**COMPONENTS OF THE CHILD PSYCHIATRIC EVALUATION**

Psychiatric evaluation of a child includes a description of the reason for the referral, the child’s past and present functioning, and any test results. An outline of the evaluation is given in Table 31.2-1.

**Identifying Data**

Identifying data for a child includes the child’s gender, age, as well as the family
constellation surrounding the child.

**History**

A comprehensive history contains information about the child’s current and past functioning from the child’s report, from clinical and structured interviews with the parents, and from information from teachers and previous treating clinicians. The chief complaint and the history of the present illness are generally obtained from both the child and the parents. Naturally, the child will articulate the situation according to his or her developmental level. The developmental history is more accurately obtained from the parents. Psychiatric and medical histories, current physical examination findings, and immunization histories can be augmented with reports from psychiatrists and pediatricians who have treated the child in the past. The child’s report is critical in understanding the current situation regarding peer relationships and adjustment to school. Adolescents are the best informants regarding knowledge of safe sexual practices, drug or alcohol use, and suicidal ideation. The family’s psychiatric and social histories, and family function are best obtained from the parents.

**Mental Status Examination**

A detailed description of the child’s current mental functioning can be obtained through observation and specific questioning. An outline of the mental status examination is presented in Table 31.2-2. Table 31.2-3 lists components of a comprehensive neuropsychiatry mental status.

</tr>
</tbody>
</table>

*
Physical Appearance. The examiner should document the child’s size, grooming, nutritional state, bruising, head circumference, physical signs of anxiety, facial expressions, and mannerisms.
Parent–Child Interaction. The examiner can observe the interactions between parents and child in the waiting area before the interview and in the family session. The manner in which parents and child converse and the emotional overtones are pertinent.

Separation and Reunion. The examiner should note both the manner in which the child responds to the separation from a parent for an individual interview and the reunion behavior. Either lack of affect at separation and reunion or severe distress on separation or reunion can indicate problems in the parent–child relationship or other psychiatric disturbances.

Orientation to Time, Place, and Person. Impairments in orientation can reflect organic damage, low intelligence, or a thought disorder. The age of the child must be kept in mind, however, because very young children are not expected to know the date, other chronological information, or the name of the interview site.

Speech and Language. The examiner should evaluate the child’s speech and language acquisition. Is it appropriate for the child’s age? A disparity between expressive language usage and receptive language is notable. The examiner should also note the child’s rate of speech, rhythm, latency to answer, spontaneity of speech, intonation, articulation of words, and prosody. Echolalia, repetitive stereotypical phrases, and unusual syntax are important psychiatric findings. Children who do not use words by age 18 months or who do not use phrases by age 2.5 to 3 years, but who have a history of normal babbling and responding appropriately to nonverbal cues, are probably developing normally. The examiner should consider the possibility that a hearing loss is contributing to a speech and language deficit.

Mood. A child’s sad expression, lack of appropriate smiling, tearfulness, anxiety, euphoria, and anger are valid indicators of mood, as are verbal admissions of feelings. Persistent themes in play and fantasy also reflect the child’s mood.

Affect. The examiner should note the child’s range of emotional expressivity, appropriateness of affect to thought content, ability to move smoothly from one affect to another, and sudden labile emotional shifts.

Thought Process and Content. In evaluating a thought disorder in a child, the clinician must always consider what is developmentally expected for the child’s age and what is deviant for any age group. The evaluation of thought form considers loosening of associations, excessive magical thinking, perseveration, echolalia, the ability to distinguish fantasy from reality, sentence coherence, and the ability to reason logically. The evaluation of thought content considers delusions, obsessions, themes, fears, wishes, preoccupations, and interests.

Suicidal ideation is always a part of the mental status examination for children who are sufficiently verbal to understand the questions and old enough to understand the
concept. Children of average intelligence who are older than 4 years of age usually have some understanding of what is real and what is make-believe and may be asked about suicidal ideation, although a firm concept of the permanence of death may not be present until several years later.

Aggressive thoughts and homicidal ideation are assessed here. Perceptual disturbances, such as hallucinations, are also assessed. Very young children are expected to have short attention spans and may change the topic and conversation abruptly without exhibiting a symptomatic flight of ideas. Transient visual and auditory hallucinations in very young children do not necessarily represent major psychotic illnesses, but they do deserve further investigation.

**Social Relatedness.** The examiner assesses the appropriateness of the child’s response to the interviewer, general level of social skills, eye contact, and degree of familiarity or withdrawal in the interview process. Overly friendly or familiar behavior may be as troublesome as extremely retiring and withdrawn responses. The examiner assesses the child’s self-esteem, general and specific areas of confidence, and success with family and peer relationships.

**Motor Behavior.** The motor behavior part of the mental status examination includes observations of the child’s coordination and activity level and ability to pay attention and carry out developmentally appropriate tasks. It also involves involuntary movements, tremors, motor hyperactivity, and any unusual focal asymmetries of muscle movement.

**Cognition.** The examiner assesses the child’s intellectual functioning and problem-solving abilities. An approximate level of intelligence can be estimated by the child’s general information, vocabulary, and comprehension. For a specific assessment of the child’s cognitive abilities, the examiner can use a standardized test.

**Memory.** School-age children should be able to remember three objects after 5 minutes and to repeat five digits forward and three digits backward. Anxiety can interfere with the child’s performance, but an obvious inability to repeat digits or to add simple numbers may reflect brain damage, mental retardation, or learning disabilities.

**Judgment and Insight.** The child’s view of the problems, reactions to them, and suggested solutions may give the clinician a good idea of the child’s judgment and insight. In addition, the child’s understanding of what he or she can realistically do to help and what the clinician can do adds to the assessment of the child’s judgment.

**Neuropsychiatric Assessment**

A neuropsychiatric assessment is appropriate for children who are suspected of having a psychiatric disorder that coexists with neuropsychiatric impairment, or psychiatric
symptoms that may be caused by neuropsychiatric dysfunction, or a neurologic disorder. Although a neuropsychiatric assessment is not sufficient in most cases to make a psychiatric diagnosis, neuropsychological profiles have been, in some cases correlated with particular psychiatric symptoms and syndromes. For example, neuropsychological differences in executive function, language and memory functions, as well as measures of mood and anxiety, have been found between youth with histories of childhood maltreatment and those without it. The neuropsychiatric evaluation combines information from neurological, neuropsychological testing, and mental status examinations. The neurological examination can identify asymmetrical abnormal signs (hard signs) that may indicate lesions in the brain. A physical examination can evaluate the presence of physical stigmata of particular syndromes in which neuropsychiatric symptoms or developmental aberrations play a role (e.g., fetal alcohol syndrome, Down syndrome). In a study of 119 youth with either early onset schizophrenia or schizoaffective disorder, by Hooper and colleagues, significantly high rates of deficits in intellectual function and academic skills were found, and the severity of these deficits was mildly correlated with severity of their psychiatric illness.

A neuropsychiatric examination also includes neurological soft signs and minor physical anomalies. The term *neurological soft signs* was first noted by Loretta Bender in the 1940s in reference to nondiagnostic abnormalities in the neurological examinations of children with schizophrenia. Soft signs do not indicate focal neurological disorders, but they are associated with a wide variety of developmental disabilities and occur frequently in children with low intelligence, learning disabilities, and behavioral disturbances. Soft signs may refer to both behavioral symptoms (which are sometimes associated with brain damage, such as severe impulsivity and hyperactivity), physical findings (including contralateral overflow movements), and a variety of nonfocal signs (e.g., mild choreiform movements, poor balance, mild incoordination, asymmetry of gait, nystagmus, and the persistence of infantile reflexes). Soft signs can be divided into those that are normal in a young child, but become abnormal when they persist in an older child, and those that are abnormal at any age. The *Physical and Neurological Examination for Soft Signs* (PANESS) is an instrument used with children up to the age of 15 years. It consists of 15 questions about general physical status and medical history and 43 physical tasks (e.g., touch your finger to your nose, hop on one foot to the end of the line, tap quickly with your finger). Neurological soft signs are important to note, but they are not useful in making a specific psychiatric diagnosis.

Minor physical anomalies or dysmorphic features occur with a higher than usual frequency in children with developmental disabilities, learning disabilities, speech and language disorders, and hyperactivity. As with soft signs, the documentation of minor physical anomalies is part of the neuropsychiatric assessment, but it is rarely helpful in the diagnostic process and does not imply a good or bad prognosis. Minor physical anomalies include a high-arched palate, epicanthal folds, hypertelorism, low-set ears, transverse palmar creases, multiple hair whorls, a large head, a furrowed tongue, and partial syndactyl of several toes.

When a seizure disorder is being considered in the differential diagnosis or a structural
abnormality in the brain is suspected, electroencephalography (EEG), computed tomography (CT), or magnetic resonance imaging (MRI) may be indicated.

**Developmental, Psychological, and Educational Testing**

Psychological testing, structured developmental assessments and achievement testing are valuable in evaluating a child’s developmental level, intellectual functioning, and academic difficulties. A measure of adaptive functioning (including the child’s competence in communication, daily living skills, socialization, and motor skills) is the most definitive way to determine the level of intellectual disability in a child. **Table 31.2-4** outlines the general categories of psychological tests.

Development Tests for Infants and Preschoolers. The Gesell Infant Scale, the Cattell Infant Intelligence Scale, Bayley Scales of Infant Development, and the Denver Developmental Screening Test include developmental assessments of infants as young as 2 months of age. When used with very young infants, the tests focus on sensorimotor and social responses to a variety of objects and interactions. When these instruments are used with older infants and preschoolers, emphasis is placed on language acquisition. The Gesell Infant Scale measures development in four areas: motor, adaptive functioning, language, and social.

An infant’s score on one of these developmental assessments is not a reliable way to...
predict a child’s future intelligence quotient (IQ) in most cases. Infant assessments are valuable, however, in detecting developmental deviation and mental retardation and in raising suspicions of a developmental disorder. Whereas infant assessments rely heavily on sensorimotor functions, intelligence testing in older children and adolescents includes later-developing functions, including verbal, social, and abstract cognitive abilities.

**Intelligence Tests for School-Age Children and Adolescents.** The most widely used test of intelligence for school-age children and adolescents is the third edition of the *Wechsler Intelligence Scale for Children* (WISC-III-R). It can be given to children from 6 to 17 years of age and yields a verbal IQ, a performance IQ, and a combined full-scale IQ. The verbal subtests consist of vocabulary, information, arithmetic, similarities, comprehension, and digit span (supplemental) categories. The performance subtests include block design, picture completion, picture arrangement, object assembly, coding, mazes (supplemental), and symbol search (supplemental). The scores of the supplemental subtests are not included in the computation of IQ.

Each subcategory is scored from 1 to 19, with 10 being the average score. An average full-scale IQ is 100; 70 to 80 represents borderline intellectual function; 80 to 90 is in the low average range; 90 to 109 is average; 110 to 119 is high average; and above 120 is in the superior or very superior range. The multiple breakdowns of the performance and verbal subscales allow great flexibility in identifying specific areas of deficit and scatter in intellectual abilities. Because a large part of intelligence testing measures abilities used in academic settings, the breakdown of the WISC-III-R can also be helpful in pointing out skills in which a child is weak and may benefit from remedial education.

The *Stanford-Binet Intelligence Scale* covers an age range from 2 to 24 years. It relies on pictures, drawings, and objects for very young children and on verbal performance for older children and adolescents. This intelligence scale, the earliest version of an intelligence test of its kind, leads to a mental age score as well as an intelligence quotient.

The *McCarthy Scales of Children’s Abilities* and the *Kaufman Assessment Battery for Children* are two other intelligence tests that are available for preschool and school-age children. They do not cover the adolescent age group.

**Long-term Stability of Intelligence.** Although a child’s intelligence is relatively stable throughout the school-age years and adolescence, some factors can influence intelligence and a child’s score on an intelligence test. The intellectual functions of children with severe mental illnesses and of those from deprived and neglectful environments may decrease over time, whereas the IQs of children with intensively enriched environments, may increase over time. Factors that influence a child’s score on a given test of intellectual functioning and, thus, affect the accuracy of the test are motivation, emotional state, anxiety, and cultural milieu. The interactions between cognitive ability and anxiety, and depression and psychosis are complex. One study of 4,405 youth from the Canadian National Longitudinal Study of Children and Youth (NLSCY), by Weeks and colleagues (2013) found that greater cognitive ability was associated with less risk
for anxiety and depressive symptoms in youth from 12 years to 13 years of age, however, by age 14 years to 15 years, cognitive ability had no effect on the odds of anxiety or depression.

**Perceptual and Perceptual Motor Tests.** The *Bender Visual Motor Gestalt Test* can be given to children between the ages of 4 and 12 years. The test consists of a set of spatially related figures that the child is asked to copy. The scores are based on the number of errors. Although not a diagnostic test, it is useful in identifying developmentally age-inappropriate perceptual performances.

**Personality Tests.** Personality tests are not of much use in making diagnoses, and they are less satisfactory than intelligence tests with regard to norms, reliability, and validity, but they can be helpful in eliciting themes and fantasies. The Rorschach test is a projective technique in which ambiguous stimuli—a set of bilaterally symmetrical inkblots—are shown to a child, who is then asked to describe what he or she sees in each. The hypothesis is that the child’s interpretation of the vague stimuli reflects basic characteristics of personality. The examiner notes the themes and patterns.

A more structured projective test is the *Children’s Apperception Test* (CAT), which is an adaptation of the *Thematic Apperception Test* (TAT). The CAT consists of cards with pictures of animals in scenes that are somewhat ambiguous, but are related to parent–child and sibling issues, caretaking, and other relationships. The child is asked to describe what is happening and to tell a story about the scene. Animals are used because it was hypothesized that children might respond more readily to animal images than to human figures.

Drawings, toys, and play are also applications of projective techniques that can be used during the evaluation of children. Dollhouses, dolls, and puppets have been especially helpful in allowing a child a nonconversational mode in which to express a variety of attitudes and feelings. Play materials that reflect household situations are likely to elicit a child’s fears, hopes, and conflicts about the family.

Projective techniques have not fared well as standardized instruments. Rather than being considered tests, projective techniques are best considered as additional clinical modalities.

**Educational Tests.** Achievement tests measure the attainment of knowledge and skills in a particular academic curriculum. The *Wide-Range Achievement Test-Revised* (WRAT-R) consists of tests of knowledge and skills and timed performances of reading, spelling, and mathematics. It is used with children from 5 years of age to adulthood. The test yields a score that is compared with the average expected score for the child’s chronological age and grade level.

The *Peabody Individual Achievement Test* (PIAT) includes word identification, spelling, mathematics, and reading comprehension.

The *Kaufman Test of Educational Achievement*, the *Gray Oral Reading Test-Revised*...
(GORT-R), and the *Sequential Tests of Educational Progress* (STEP) are achievement tests that determine whether a child has achieved the educational level expected for his or her grade level. Children whose achievement is significantly lower than expected for their grade level in one or more subjects, often exhibit a specific learning disorder.

**Biopsychosocial Formulation.** A clinician’s task is to integrate all of the information obtained into a formulation that takes into account the biological predisposition, psychodynamic factors, environmental stressors, and life events that have led to the child’s current level of functioning. Psychiatric disorders and any specific physical, neuromotor, or developmental abnormalities must be considered in the formulation of etiologic factors for current impairment. The clinician’s conclusions are an integration of clinical information along with data from standardized psychological and developmental assessments. The psychiatric formulation includes an assessment of family function as well as the appropriateness of the child’s educational setting. A determination of the child’s overall safety in his or her current situation is made. Any suspected maltreatment must be reported to the local child protective service agency. The child’s overall well-being regarding growth, development, and academic and play activities is considered.

**Diagnosis**

Structured and semistructured (evidence-based) assessment tools often enhance a clinician’s ability to make the most accurate diagnoses. These instruments, described earlier, include the K-SADS, the CAPA, and the NIMH DISC-IV interviews. The advantages of including an evidence-based instrument in the diagnostic process include decreasing potential clinician bias to make a diagnosis without all of the necessary symptoms information, and serving as guides for the clinician to consider each symptom that could contribute to a given diagnosis. These data can enable the clinician to optimize his expertise to make challenging judgments regarding child and adolescent disorders, which may possess overlapping symptoms. The clinician’s ultimate task includes making all appropriate diagnoses according to the DSM-5. Some clinical situations do not fulfill criteria for DSM-5 diagnoses, but cause impairment and require psychiatric attention and intervention. Clinicians who evaluate children are frequently in the position of determining the impact of behavior of family members on the child’s well-being. In many cases, a child’s level of impairment is related to factors extending beyond a psychiatric diagnosis, such as the child’s adjustment to his or her family life, peer relationships, and educational placement.

**RECOMMENDATIONS AND TREATMENT PLAN**

The recommendations for treatment are derived by a clinician who integrates the data gathered during the evaluation into a coherent formulation of the factors that are contributing to the child’s current problems, the consequences of the problems, and strategies that may ameliorate the difficulties. The recommendations can be broken
down into their biological, psychological, and social components. That is, identification of a biological predisposition to a particular psychiatric disorder may be clinically relevant to inform a psychopharmacologic recommendation. As part of the formulation, an understanding of the psychodynamic interactions between family members may lead a clinician to recommend treatment that includes a family component. Educational and academic problems are addressed in the formulation and may lead to a recommendation to seek a more effective academic placement. The overall social situation of the child or adolescent is taken into account when recommendations for treatment are developed. Of course, the physical and emotional safety of a child or adolescent is of the utmost importance and always at the top of the list of recommendations.

The child or adolescent’s family, school life, peer interactions, and social activities often have a direct impact on the child’s success in overcoming his or her difficulties. The psychological education and cooperation of a child or adolescent’s family are essential ingredients in successful application of treatment recommendations. Communications from clinicians to parents and family members that balance the observed positive qualities of the child and family with the weak areas are often perceived as more helpful than a focus only on the problem areas. Finally, the most successful treatment plans are those developed cooperatively between the clinician, child, and family members during which each member of the team perceives that he or she has been given credit for positive contributions.

31.3 Intellectual Disability

Intellectual disability, formerly known as mental retardation, can be caused by a range of environmental and genetic factors that lead to a combination of cognitive and social impairments. The American Association on Intellectual and Developmental Disability (AAIDD) defines intellectual disability as a disability characterized by significant limitations in both intellectual functioning (reasoning, learning, and problem solving) and in adaptive behavior (conceptual, social, and practical skills) that emerges before the age of 18 years. Wide acceptance of this definition has led to the international consensus that an assessment of both social adaptation and intelligence quotient (IQ) are necessary to determine the level of intellectual disability. Measures of adaptive function assess competency in social functioning, understanding of societal norms, and performance of everyday tasks, whereas measures of intellectual function focus on cognitive abilities. Although individuals with a given intellectual level do not all have identical levels of adaptive function, epidemiologic data suggest that prevalence of intellectual disability is largely determined by intellectual level and a level of adaptive function, which typically corresponds closely with cognitive ability.

In the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), various levels of severity of intellectual disability are determined on the basis of adaptive functioning, not on IQ scores. This change in emphasis from prior diagnostic manuals has been adopted by DSM-5 because adaptive functioning determines the level
of support that is required. Furthermore, IQ scores are less valid in the lower portions of the IQ range. Making a determination of severity level of intellectual disability, according to DSM-5, includes assessment of functioning in a conceptual domain (e.g., academic skills), a social domain (e.g., relationships), and a practical domain (e.g., personal hygiene).

Societal approaches to children with intellectual disability have shifted significantly over time. Historically, in the mid-1800s many children with intellectual disability were placed in residential educational facilities based on the belief that with sufficient intensive training, these children would be able to return to their families and function in society at a higher level. However, the expectation of educating these children in order to overcome their disabilities was not realized. Gradually, many residential programs increased in size, and eventually the focus began to shift from intensive education to more custodial care. Residential settings for children with intellectual disability received their maximal use in the mid-1900s, until public awareness of the crowded, unsanitary, and, in some cases, abusive conditions sparked the movement toward “deinstitutionalization.” An important force in the deinstitutionalization of children with intellectual disability was the philosophy of “normalization” in living situations, and “inclusion” in educational settings. Since the late 1960s, few children with intellectual disability have been placed in residences, and the concepts of normalization and inclusion remain prominent among advocacy groups and parents.

The passage of Public Law 94–142 (the Education for all Handicapped Children Act) in 1975 mandates that the public school system provide appropriate educational service to all children with disabilities. The Individuals with Disabilities Act in 1990 extended and modified the above legislation. Currently, provision of public education for all children, including those with disabilities, “within the least restrictive environment” is mandated by law.

In addition to the educational system, advocacy groups, including the Council for Exceptional Children (CEC) and the National Association for Retarded Citizens (NARC) are well known parental lobbying organizations for children with intellectual disability and were instrumental in advocating for Public Law 94–142. The American Association on Intellectual and Developmental Disabilities, formerly known as The American Association on Intellectual disability (AAMR), is the most prominent advocacy organization in this field. It has been very influential in educating the public about, and in supporting research and legislation relating to, intellectual disability.

The AAIDD promotes a view of intellectual disability as a functional interaction between an individual and the environment, rather than a static designation of a person’s limitations. Within this conceptual framework, a child or adolescent with intellectual disability is determined to need intermittent, limited, extensive, or pervasive “environmental support” with respect to a specific set of adaptive function domains. These include communication, self-care, home living, social or interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety.

created a forum to promote the full social inclusion of people with intellectual disability. Through its recognition and focus on social barriers, this international forum aims to provide protections for individuals with intellectual disability, and to seek more inclusion of those with intellectual disability in social, civic, and educational activities.

**NOMENCLATURE**

The accurate definition of intellectual disability has been a challenge for clinicians over the centuries. All current classification systems underscore that intellectual disability is based on more than cognitive deficits, that is, it also includes impaired social adaptive function. According to DSM-5, a diagnosis of intellectual disability should be made only when there are deficits in intellectual functioning and deficits in adaptive functioning (Table 31.3-1). Once intellectual disability is recognized, the level of severity is determined by the level of adaptive functional impairment.

<table>
<thead>
<tr>
<th>Intellectual disability (intellectual development disorder) is a disorder with onset during the developmental period that includes both intellectual and adaptive functioning deficits in conceptual, social, and practical domains. The following three criteria must be met:</th>
</tr>
</thead>
<tbody>
<tr>
<td>A. Deficits in intellectual functions, such as reasoning, problem solving, planning, abstract thinking, judgment, academic learning, and learning from experience, confirmed by both clinical assessment and individualized, standardized intelligence testing.</td>
</tr>
<tr>
<td>B. Deficits in adaptive functioning that result in failure to meet developmental and sociocultural standards for personal independence and social responsibility. Without ongoing support, the adaptive deficits limit functioning in one or more activities of daily life, such as communication, social participation, and independent living, across multiple environments, such as home, school, work, and community.</td>
</tr>
<tr>
<td>C. Onset of intellectual and adaptive deficits during the developmental period.</td>
</tr>
</tbody>
</table>

**Note:** The diagnostic term intellectual disability is the equivalent term for the ICD-11 diagnosis of intellectual developmental disorder. Although the term intellectual disability is used throughout this manual, both terms are used in the title to clarify relationships with other classification systems. Moreover, a federal statute in the United States (Public Law 111–256, Rosa’s Law) replaces the term mental retardation with intellectual disability, and research journals use the term intellectual disability. Thus, intellectual disability is the term in common use by medical, educational, and other professions and by the lay public and advocacy groups.

Specify current severity: |
| 317 (F70) Mild |
| 318.0 (F71) Moderate |
| 318.1 (F72) Severe |
| 318.2 (F73) Profound |

---

*Table 31.3-2: Developmental Characteristics of Intellectual Disability*
If the clinician chooses to use a standardized test of intelligence—which is still common practice—the term *significantly subaverage* is defined as an IQ of approximately 70 or below or two standard deviations below the mean for the particular test. Adaptive functioning can be measured by using a standardized scale, such as the *Vineland Adaptive Behavior Scale*. This scale scores communications, daily living skills, socialization, and motor skills (up to 4 years, 11 months) and generates an adaptive behavior composite that is correlated with the expected skills at a given age.

Approximately 85 percent of individuals who have intellectual disability fall within the DSM-5 mild intellectual disability category. This is typically defined by a Full Scale IQ between 50 and 70 and an adaptive function severity in the mild range. Adaptive function includes skills such as communication, self-care, social skills, work, leisure, and understanding of safety. Intellectual disability is influenced by genetic, environmental, and psychosocial factors. A host of subtle environmental and developmental factors, including subclinical lead intoxication and prenatal exposure to drugs, alcohol, and other toxins have been implicated as contributors to intellectual disability. Certain genetic syndromes associated with intellectual disability such as fragile X syndrome, Down syndrome, and Prader-Willi syndrome, have characteristic patterns of social, linguistic, and cognitive development and typical behavioral manifestations.

**DEGREES OF SEVERITY OF INTELLECTUAL DISABILITY**

The severity levels of intellectual disability are expressed in DSM-5 as mild, moderate, severe, and profound. “Borderline intellectual functioning,” a term previously used to describe individuals with a full scale IQ in the range of 70 to 80, is no longer described as a diagnosis in DSM-5. The term is used in DSM-5 as a condition that may be the focus of clinical attention; however, no criteria are given.

<table>
<thead>
<tr>
<th>Level of Intellectual Disability</th>

<th>School Age (6 to 20 yrs) Training and Education</th>
<th>Adult (21 yrs and Above) Social and Vocational Adequacy</th>
</tr>
</thead>
<tbody>
<tr>
<td>Profound</td>
<td>Gross disability; minimal capacity for functioning in sensorimotor areas; needs nursing care; constant aid and supervision required</td>
<td>Some motor development present; may respond to minimal or limited training in self-help</td>
<td>Some motor and speech development; may achieve very limited self-care; needs nursing care</td>
</tr>
<tr>
<td>Severe</td>
<td>Poor motor development; speech minimal; generally unable to profit from training in self-help; little or no communication skills</td>
<td>Can talk or learn to communicate; can be trained in elemental health habits; profits from systematic habit training; unable to profit from vocational training</td>
<td>May contribute partially to self-maintenance under complete supervision; can develop self-protection skills to a minimal useful level in controlled environment</td>
</tr>
<tr>
<td>Moderate</td>
<td>Can talk or learn to communicate; poor social awareness; fair motor development; profits from training in self-help; can be managed with moderate supervision</td>
<td>Can profit from training in social and occupational skills; unlikely to progress beyond second-grade level in academic subjects; may learn to travel alone in familiar places</td>
<td>May achieve self-maintenance in unskilled or semiskilled work under sheltered conditions; needs supervision and guidance when under mild social or economic stress</td>
</tr>
<tr>
<td>Mild</td>
<td>Can develop social and communication skills; minimal retardation in sensorimotor areas; often not distinguished from normal until later age</td>
<td>Can learn academic skills up to approximately sixth-grade level by late teens; can be guided toward social conformity</td>
<td>Can usually achieve social and vocational skills adequate to minimal self-support, but may need guidance and assistance when under unusual social or economic stress</td>
</tr>
</tbody>
</table>

Mild intellectual disability represents approximately 85 percent of persons with intellectual disability. Children with mild intellectual disability often are not identified until the first or second grade, when academic demands increase. By late adolescence, they often acquire academic skills at approximately a sixth-grade level. Specific causes for the intellectual disability are often unidentified in this group. Many adults with mild intellectual disability can live independently with appropriate support and raise their own families. IQ for this level of adaptive function may typically range from 50 to 70.

Moderate intellectual disability represents about 10 percent of persons with intellectual disability. Most children with moderate intellectual disability acquire language and can communicate adequately during early childhood. They are challenged academically and often are not able to achieve above a second to third grade level. During adolescence, socialization difficulties often set these persons apart, and a great deal of social and vocational support is beneficial. As adults, individuals with moderate intellectual disability may be able to perform semiskilled work under appropriate supervision. IQ for this level of adaptive function may typically range from 35 to 50.

Severe intellectual disability represents about 4 percent of individuals with intellectual disability. They may be able to develop communication skills in childhood and often can learn to count as well as recognize words that are critical to functioning. In this group, the cause for the intellectual disability is more likely to be identified than in milder forms of intellectual disability. In adulthood, persons with severe intellectual disability may adapt well to supervised living situations, such as group homes, and may be able to perform work-related tasks under supervision. IQ in individuals with this level of adaptive function may typically range from 20 to 35.

Profound intellectual disability constitutes approximately 1 to 2 percent of individuals with intellectual disability. Most individuals with profound intellectual disability have identifiable causes for their condition. Children with profound intellectual disability may be taught some self-care skills and learn to communicate their needs given the appropriate training. IQ in individuals with this level of adaptive function may typically be less than 20.

The DSM-5 also includes a disorder called “Unspecified Intellectual Disability” (Intellectual Developmental Disorder), reserved for individuals over the age of 5 years who are difficult to evaluate but are strongly suspected of having intellectual disability. Individuals with this diagnosis may have sensory or physical impairments such as blindness or deafness, or concurrent mental disorders, making it difficult to administer typical assessment tools. (e.g., Bayley Scales of Infant Development and Cattell Infant Scale) to aid in determining adaptive functional impairment.

EPIDEMIOLOGY

The majority of population-based prevalence estimates for intellectual disability in developing countries range from 10 to 15 per 1,000 children. The prevalence of intellectual disability at any one time is estimated to range from 1 to 3 percent of the population in Western societies. The incidence of intellectual disability is difficult to
accurately calculate because mild disabilities may be unrecognized until middle childhood. In some cases, even when intellectual function is limited, social adaptive skills may not be challenged until late childhood or early adolescence, and the diagnosis is not made until that time. The highest incidence of intellectual disability is reported in school-age children, with the peak at ages 10 to 14 years. Intellectual disability is about 1.5 times more common among males than females.
COMORBIDITY

Prevalence

Epidemiological surveys indicate that up to two thirds of children and adults with intellectual disability have comorbid psychiatric disorders; and this rate is several times higher than that in community samples without intellectual disability. The prevalence of psychopathology appears to be correlated with the severity of intellectual disability; the more severe the intellectual disability, the higher the risk for coexisting psychiatric disorders. An epidemiological study found that 40.7 percent of intellectually disabled children between 4 and 18 years of age met criteria for at least one additional psychiatric disorder. The severity of intellectual disability influenced the risk for particular comorbid psychiatric disorders. Disruptive and conduct-disorder behaviors occurred more frequently in those diagnosed with mild intellectual disability, whereas those with more severe intellectual disability were more likely to meet criteria for autism spectrum disorder and exhibited symptoms such as self-stimulation and self-mutilation. Comorbidity of psychiatric disorders with intellectual disability in children in this study was not correlated with age or gender. Children diagnosed with profound intellectual disability were less likely to exhibit comorbid psychiatric disorders.

Psychiatric disorders among persons with intellectual disability are varied, and include mood disorders, schizophrenia, attention-deficit/hyperactivity disorder (ADHD), and conduct disorder. Children diagnosed with severe intellectual disability have a particularly high rate of comorbid autism spectrum disorder. Approximately 2 to 3 percent of those with intellectual disability meet diagnostic criteria for schizophrenia, which is several times higher than the rate for the general population. Up to 50 percent of children and adults with intellectual disability are found to meet criteria for a mood disorder when instruments such as the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS), the Beck Depression Inventory, and the Children’s Depression Inventory were used in studies. However, a limitation of these studies is that these instruments have not been standardized within intellectual disability populations. Frequent psychiatric symptoms that occur in children with intellectual disability, outside the context of a full psychiatric disorder, include hyperactivity and short attention span, self-injurious behaviors (e.g., head-banging and self-biting), and repetitive stereotypical behaviors (hand-flapping and toe-walking). In children and adults with milder forms of intellectual disability, negative self-image, low self-esteem, poor frustration tolerance, interpersonal dependence, and a rigid problem-solving style are frequent.

Neurological Disorders

Seizure disorders occur more frequently in individuals with intellectual disability than in the general population, and prevalence rates for seizures increase proportionally to severity level of intellectual disability. A review of psychiatric disorders in children and adolescents with intellectual disability and epilepsy, found that approximately one third
had comorbid autism spectrum disorder. The combination of intellectual disability, epilepsy, and autism spectrum disorder has been estimated to occur in 0.07 percent of the general population.

**Psychosocial Features**

A negative self-image and poor self-esteem are common features of mildly and moderately intellectually disabled persons who are aware of their social and academic differences from others. Given their experience of repeated failure and disappointment in being unable to meet their parents’ and society’s expectations, they may also be faced with falling progressively behind younger siblings. Communication difficulties further increase their vulnerability to feelings of ineptness and frustration. Inappropriate behaviors, such as withdrawal, are common. The perpetual sense of isolation and inadequacy has been linked to feelings of anxiety, anger, dysphoria, and depression.

**ETIOLOGY**

Etiological factors in intellectual disability can be genetic, developmental, environmental, or a combination. Genetic causes include chromosomal and inherited conditions; developmental and environmental factors include prenatal exposure to infections and toxins; and environmental or acquired factors include prenatal trauma (e.g., prematurity) and sociocultural factors. The severity of intellectual disability may be related to the timing and duration of a given trauma as well as to the degree of exposure to the central nervous system (CNS). In about three fourths of persons diagnosed with severe intellectual disability, the etiology is known, whereas the etiology is apparent in up to half of those diagnosed with mild intellectual disability. A study of 100 consecutive children diagnosed with intellectual disability admitted to a clinical genetics unit of a university pediatric hospital reported that in 41 percent of cases, a causative diagnosis was made. No cause is known for three fourths of persons with IQ ranging from 70 to 80 and variable adaptive functioning. Among chromosomal disorders, Down syndrome and fragile X syndrome are the most common disorders that usually produce at least moderate intellectual disability. A prototype of a metabolic disorder associated with intellectual disability is phenylketonuria (PKU). Deprivation of nutrition, nurturance, and social stimulation can potentially contribute to the development of at least mild forms of intellectual disability. Current knowledge suggests that genetic, environmental, biological, and psychosocial factors work additively in the emergence of intellectual disability.

**Genetic Etiological Factors in Intellectual Disability**

**Single-Gene Causes.** One of the most well-known single gene causes of intellectually disability is found in the \textit{FMR1} gene whose mutations cause fragile X syndrome. It is the most common and first X-linked gene to be identified as a direct cause of intellectual disability. Abnormalities in autosomal chromosomes are frequently
associated with intellectual disability, whereas aberrations in sex chromosomes can result in characteristic physical syndromes that do not include intellectual disability (e.g., Turner’s syndrome with XO and Klinefelter’s syndrome with XXY, XXXY, and XXYY variations). Some children with Turner’s syndrome have normal to superior intelligence. Agreement exists on a few predisposing factors for chromosomal disorders—among them, advanced maternal age, increased age of the father, and X-ray radiation.

**Visible and Submicroscopic Chromosomal Causes of Intellectual Disability.** Trisomy 21 (Down syndrome) is a prototype of a cytogenetically visible abnormality that accounts for about two-thirds of the 15 percent of intellectual disability attributable to visible abnormal cytogenetics. Other microscopically visible chromosomal abnormalities associated with intellectual disability include deletions, translocations, and supernumerary marker chromosomes. Typically, microscopic chromosome analysis is able to identify abnormalities of 5 to 10 million base pairs or greater.

Submicroscopic identification requires the use of microarrays that can identify losses of chromosomal segments too small to be picked up by light microscopy. The altered copy number variants (CNVs) in submicroscopic segments of the chromosome have been identified to be associated with up to 13 to 20 percent of cases of intellectual disability. That is, the genes associated with a particular developmental abnormality have been identified to be located in the critical regions of the pathogenic copy number variants.

**Genetic Intellectual Disability and Behavioral Phenotype**

Specific and predictable behaviors have been found to be associated with certain genetically based cases of intellectual disability. These behavioral phenotypes are defined as a syndrome of observable behaviors that occur with a significantly greater probability than expected among those individuals with a specific genetic abnormality.

Examples of behavioral phenotypes occur in genetically determined syndromes such as fragile X syndrome, Prader-Willi syndrome, and Down syndrome in which specific behavioral manifestations can be expected. Persons with fragile X syndrome have extremely high rates (up to three fourths of those studied) of ADHD. High rates of aberrant interpersonal behavior and language function often meet the criteria for autistic disorder and avoidant personality disorder. Prader-Willi syndrome is almost always associated with compulsive eating disturbances, hyperphagia, and obesity. Socialization is an area of weakness, especially in coping skills. Externalizing behavior problems—such as temper tantrums, irritability, and arguing—seem to be heightened in adolescence.

**Down Syndrome.** The etiology of Down syndrome, known to be caused by an extra copy of the entire chromosome 21, makes it one of the more complex disorders. The original description of Down syndrome, first made by the English physician Langdon Down in 1866, was based on physical characteristics associated with subnormal mental functioning. Since then, Down syndrome has been the most
investigated, and most discussed, syndrome in intellectual disability. Recent data have suggested that Down syndrome may be more amenable to postnatal interventions to address the cognitive deficits that it produces than was previously thought. Although still in the early stages of animal research, data from experiments with one mouse model, the Ts65Dn, indicates that pharmacologic interventions may influence learning and memory deficits known to occur in Down syndrome.

Phenotypically, children with Down syndrome are observed to have characteristic physical attributes, including slanted eyes, epicanthal folds, and a flat nose.

The etiology of Down syndrome is complicated by the recognition of three types of chromosomal aberrations in Down syndrome:

1. Patients with trisomy 21 (three chromosomes 21, instead of the usual two) represent the overwhelming majority; they have 47 chromosomes, with an extra chromosome 21. The mothers’ karyotypes are normal. A nondisjunction during meiosis, occurring for unknown reasons, is held responsible for the disorder.

2. Nondisjunction occurring after fertilization in any cell division results in mosaicism, a condition in which both normal and trisomic cells are found in various tissues.

3. In translocation, a fusion occurs of two chromosomes, usually 21 and 15, resulting in a total of 46 chromosomes, despite the presence of an extra chromosome 21. The disorder, unlike trisomy 21, is usually inherited, and the translocated chromosome may be found in unaffected parents and siblings. The asymptomatic carriers have only 45 chromosomes.

Approximately 6,000 babies are affected with Down syndrome in the United States, which makes the incidence of Down syndrome 1 in every 700 births, or 15 per 10,000 live births. For women older than 32 years of age, the risk of having a child with Down syndrome (trisomy 21) is about 1 in 100 births, but when translocation is present, the risk is about 1 in 3. Most children with Down syndrome are mildly to moderately intellectually disabled, with a minority having an IQ above 50. Cognitive development appears to progress normally from birth to 6 months of age; IQ scores gradually decrease from near normal at 1 year of age to about 30 to 50 as development proceeds. The decline in intellectual function may not be readily apparent. Infant tests may not reveal the full extent of the deficits. According to anecdotal clinical reports, children with Down syndrome are typically placid, cheerful, and cooperative and adapt easily at home. With adolescence, the picture changes: youth with Down syndrome may experience more social and emotional difficulties and behavior disorders, and there is an increased risk for psychotic disorders.

In Down syndrome, language function is a relative weakness, whereas sociability and social skills, such as interpersonal cooperation and conformity with social conventions, are relative strengths. Children with Down syndrome typically manifest deficits in scanning the environment; they are more likely to focus on a single stimulus, leading to difficulty noticing environmental changes. A variety of comorbid psychiatric disorders emerge in persons with Down syndrome; however, the rates appear to be lower than in children with intellectual disability and autism spectrum disorder.

The diagnosis of Down syndrome is made with relative ease in an older child, but it is often difficult in newborn infants. The most important signs in a newborn include
general hypotonia; oblique palpebral fissures; abundant neck skin; a small, flattened skull; high cheekbones; and a protruding tongue. The hands are broad and thick, with a single palmar transversal crease, and the little fingers are short and curved inward. Moro reflex is weak or absent. More than 100 signs or stigmata are described in Down syndrome, but rarely are all found in one person. Commonly occurring physical problems in Down syndrome include cardiac defects, thyroid abnormalities, and gastrointestinal problems. Life expectancy was once drastically limited to about the age of 40; however, currently it is vastly increased, although still not as long as those without intellectual disability.

Down syndrome is characterized by deterioration in language, memory, self-care skills, and problem-solving by the third decade of life. Postmortem studies of individuals with Down syndrome older than age 40 have shown a high incidence of senile plaques and neurofibrillary tangles, similar to those seen in Alzheimer’s disease. Neurofibrillary tangles are known to occur in a variety of degenerative diseases, whereas senile plaques seem to be found most often in Alzheimer’s disease and in Down syndrome.

**Fragile X Syndrome.** Fragile X syndrome is the second most common single cause of intellectual disability. The syndrome results from a mutation on the X chromosome at what is known as the fragile site (Xq27.3). The fragile site is expressed in only some cells, and it may be absent in asymptomatic males and female carriers. Much variability is present in both genetic and phenotypic expression. Fragile X syndrome is believed to occur in about 1 of every 1,000 males and 1 of every 2,000 females. The typical phenotype includes a large, long head and ears, short stature, hyperextensible joints, and postpubertal macroorchidism. Associated intellectual disability ranges from mild to severe. The behavioral profile of persons with the syndrome includes a high rate of ADHD, learning disorders, and autism spectrum disorder. Deficits in language function include rapid perseverative speech with abnormalities in combining words into phrases and sentences. Persons with fragile X syndrome seem to have relatively strong skills in communication and socialization; their intellectual functions seem to decline in the pubertal period. Female carriers are often less impaired than males with fragile X syndrome, but females can also manifest the typical physical characteristics and may have mild intellectual disability.

**Prader-Willi Syndrome.** Prader-Willi syndrome is believed to result from a small deletion involving chromosome 15, occurring sporadically. Its prevalence is less than 1 in 10,000. Persons with the syndrome exhibit compulsive eating behavior and often obesity, intellectual disability, hypogonadism, small stature, hypotonia, and small hands and feet.

**Cat’s Cry (Cri-du-Chat) Syndrome.** Children with cat’s cry syndrome have a deletion in chromosome 5. They are typically severely intellectually disabled and show many signs often associated with chromosomal aberrations, such as microcephaly, low-set ears, oblique palpebral fissures, hypertelorism, and micrognathia. The characteristic
cat-like cry that gave the syndrome its name is caused by laryngeal abnormalities that gradually change and disappear with increasing age.

**Phenylketonuria.** PKU was first described by Ivar Asbjörn Folling in 1934 as an inborn error of metabolism. PKU is transmitted as a simple recessive autosomal Mendelian trait and occurs in about 1 of every 10,000 to 15,000 live births. For parents who have already had a child with PKU, the chance of having another child with PKU is 20 to 25 percent of successive pregnancies. PKU is reported predominantly in persons of North European origin; a few cases have been described in blacks, Yemenite Jews, and Asians. The basic metabolic defect in PKU is an inability to convert phenylalanine, an essential amino acid, to paratyrosine because of the absence or inactivity of the liver enzyme phenylalanine hydroxylase, which catalyzes the conversion. Therefore, PKU is largely preventable with a screening for it, which, if positive, should be followed with a low phenylalanine diet. Two other types of hyperphenylalaninemia have recently been described. One is caused by a deficiency of the enzyme dihydropteridine reductase, and the other to a deficiency of a cofactor, biopterin. The first defect can be detected in fibroblasts, and biopterin can be measured in body fluids. Both these rare disorders carry a high risk of fatality.

Most patients with PKU are severely intellectually disabled, but some are reported to have borderline or normal intelligence. Eczema, vomiting, and convulsions occur in about one third of all patients. Although the clinical picture varies, typically, children with PKU are reported to be hyperactive and irritable. They frequently exhibit temper tantrums and often display bizarre movements of their bodies and upper extremities, including twisting hand mannerisms. Verbal and nonverbal communication is commonly severely impaired or nonexistent. The children’s coordination is poor, and they have many perceptual difficulties.

Currently, the Guthrie inhibition assay is a widely applied screening test using a bacteriological procedure to detect phenylalanine in the blood. In the United States, newborn infants are routinely screened for PKU. Early diagnosis is important, because a low-phenylalanine diet, in use since 1955, significantly improves both behavior and developmental progress. The best results seem to be obtained with early diagnosis and the start of dietary treatment before the child is 6 months of age. Dietary treatment, however, is not without risk. Phenylalanine is an essential amino acid, and its omission from the diet can lead to such severe complications as anemia, hypoglycemia, or edema. Dietary treatment of PKU should be continued indefinitely. Children who receive a diagnosis before the age of 3 months and are placed on an optimal dietary regimen may have normal intelligence. A low-phenylalanine diet does not reverse intellectual disability in untreated older children and adolescents with PKU, but the diet does decrease irritability and abnormal electroencephalography (EEG) changes and does increase social responsiveness and attention span. The parents of children with PKU and some of the children’s normal siblings are heterozygous carriers.

**Rett syndrome.** Rett syndrome, now diagnosed in the DSM-5 as a form of autism
spectrum disorder, is believed to be caused by a dominant X-linked gene. It is degenerative and affects only females. In 1966, Andreas Rett reported on 22 girls with a serious progressive neurological disability. Deterioration in communications skills, motor behavior, and social functioning starts at about 1 year of age. Symptoms include ataxia, facial grimacing, teeth-grinding, and loss of speech. Intermittent hyperventilation and a disorganized breathing pattern are characteristic while the child is awake. Stereotypical hand movements, including hand-wringing, are typical. Progressive gait disturbance, scoliosis, and seizures occur. Severe spasticity is usually present by middle childhood. Cerebral atrophy occurs with decreased pigmentation of the substantia nigra, which suggests abnormalities of the dopaminergic nigrostriatal system.

**Neurofibromatosis.** Also called von Recklinghausen’s, neurofibromatosis is the most common of the neurocutaneous syndromes caused by a single dominant gene, which may be inherited or occur as a new mutation. The disorder occurs in about 1 of 5,000 births and is characterized by café au lait spots on the skin and by neurofibromas, including optic gliomas and acoustic neuromas, caused by abnormal cell migration. Mild intellectual disability occurs in up to one third of those with the disease.

**Tuberous Sclerosis.** Tuberous sclerosis is the second most common of the neurocutaneous syndromes; a progressive intellectual disability occurs in up to two thirds of all affected persons. It occurs in about 1 of 15,000 persons and is inherited by autosomal dominant transmission. Seizures are present in all those with intellectual disability, and in two thirds of those who are not. Infantile spasms may occur as early as 6 months of age. The phenotypic presentation includes adenoma sebaceum and ash-leaf spots that can be identified with a slit lamp.

**Lesch-Nyhan Syndrome.** Lesch-Nyhan syndrome is a rare disorder caused by a deficiency of an enzyme involved in purine metabolism. The disorder is X-linked; patients have intellectual disability, microcephaly, seizures, choreoathetosis, and spasticity. The syndrome is also associated with severe compulsive self-mutilation by biting the mouth and fingers. Lesch-Nyhan syndrome is another example of a genetically determined syndrome with a specific, predictable behavioral pattern.

**Adrenoleukodystrophy**
The most common of several disorders of sudanophilic cerebral sclerosis, adrenoleukodystrophy is characterized by diffuse demyelination of the cerebral white matter resulting in visual and intellectual impairment, seizures, spasticity, and progression to death. The cerebral degeneration in adrenoleukodystrophy is accompanied by adrenocortical insufficiency. The disorder is transmitted by a sex-linked gene located on the distal end of the long arm of the X chromosome. The clinical onset is generally between 5 and 8 years of age, with early seizures, disturbances in gait, and
mild intellectual impairment. Abnormal pigmentation reflecting adrenal insufficiency sometimes precedes the neurological symptoms, and attacks of crying are common. Spastic contractures, ataxia, and swallowing disturbances are also frequent. Although the course is often rapidly progressive, some patients may have a relapsing and remitting course.

**Maple Syrup Urine Disease.** The clinical symptoms of maple syrup urine disease appear during the first week of life. The infant deteriorates rapidly and has decerebrate rigidity, seizures, respiratory irregularity, and hypoglycemia. If untreated, maple syrup urine disease is usually fatal in the first months of life, and the survivors have severe intellectual disability. Some variants have been reported with transient ataxia and only mild intellectual disability. Treatment follows the general principles established for PKU and consists of a diet very low in the three involved amino acids—leucine, isoleucine, and valine.

**Other Enzyme Deficiency Disorders.** Several enzyme deficiency disorders associated with intellectual disability have been identified, and still more diseases are being added as new discoveries are made, including Hartnup disease, galactosemia, and glycogen-storage disease. Table 31.3-3 lists 30 important disorders with inborn errors of metabolism, hereditary transmission patterns, defective enzymes, clinical signs, and relation to intellectual disability.

Acquired and Developmental Factors

Prenatal Period. Important prerequisites for the overall development of the fetus include the mother’s physical, psychological, and nutritional health during pregnancy. Maternal chronic illnesses and conditions affecting the normal development of the fetus’s CNS include uncontrolled diabetes, anemia, emphysema, hypertension, and long-term use of alcohol and narcotic substances. Maternal infections during pregnancy, especially viral infections, have been known to cause fetal damage and intellectual disability. The extent of fetal damage depends on such variables as the type of viral infection, the gestational age of the fetus, and the severity of the illness. Although numerous infectious diseases have been reported to affect the fetus’s CNS, the following maternal illnesses have been identified to increase risk of intellectual disability in the newborn.

Rubella (German measles). Rubella has replaced syphilis as the major cause of congenital malformations and intellectual disability caused by maternal infection. The
children of affected mothers may show several abnormalities, including congenital heart disease, intellectual disability, cataracts, deafness, microcephaly, and microphthalmia. Timing is crucial, because the extent and frequency of the complications are inversely related to the duration of the pregnancy at the time of maternal infection. When mothers are infected in the first trimester of pregnancy, 10 to 15 percent of the children are affected, but the incidence rises to almost 50 percent when the infection occurs in the first month of pregnancy. The situation is often complicated by subclinical forms of maternal infection that go undetected. Maternal rubella can be prevented by immunization.

Cytomegalic Inclusion Disease. In many cases, cytomegalic inclusion disease remains dormant in the mother. Some children are stillborn, and others have jaundice, microcephaly, hepatosplenomegaly, and radiographic findings of intracerebral calcification. Children with intellectual disability from the disease frequently have cerebral calcification, microcephaly, or hydrocephalus. The diagnosis is confirmed by positive findings of the virus in throat and urine cultures and the recovery of inclusion-bearing cells in the urine.

Syphilis. Syphilis in pregnant women was once the main cause of various neuropathological changes in their offspring, including intellectual disability. Today, the incidence of syphilitic complications of pregnancy fluctuates with the incidence of syphilis in the general population. Some recent alarming statistics from several major cities in the United States indicate that there is still no room for complacency.

Toxoplasmosis. Toxoplasmosis can be transmitted by the mother to the fetus. It causes mild or severe intellectual disability and, in severe cases, hydrocephalus, seizures, microcephaly, and chorioretinitis.

Herpes Simplex. The herpes simplex virus can be transmitted transplacentally, although the most common mode of infection is during birth. Microcephaly, intellectual disability, intracranial calcification, and ocular abnormalities may result.

Human Immunodeficiency Virus (HIV). Cognitive impairments are well known to be associated with transmission of HIV from mothers to their babies. HIV may have both direct and indirect influences on the developing brain. A subset of infants born infected with HIV may develop progressive encephalopathy, intellectual disabilities, and seizures within the first year of life. Fortunately, over the last two decades, there has been a dramatic decrease in perinatal HIV transmission due to a combination of antiviral agents provided to mothers during pregnancy and delivery, obstetric interventions that reduce risk, and administration of zidovudine (ZDV) as a prophylaxis for six weeks to newborns exposed to HIV. In the United States, the highest rate of reported pediatric acquired immunodeficiency disease (AIDS) occurred in 1992, with 1,700 cases reported compared to less than 50 cases reported annually now. In the
United States, fewer than 300 cases of HIV transmission from mother to child were reported in 2005. However, vertical transmission of HIV from mother to child around the world, especially in Africa, is considerable. Most babies born to HIV-infected mothers in the United States are not infected with the virus.

**Fetal Alcohol Syndrome.** Fetal alcohol syndrome (FAS) results from prenatal alcohol exposure and can lead to a wide range of problems in the newborn. According to the Centers for Disease Control and Prevention, FAS in the United States occurs at a rate ranging from 0.2 to 1.5 per 1,000 live births. FAS is one of the leading preventable causes of intellectual disability and physical disabilities. The typical phenotypic picture of a child with FAS includes facial dysmorphism comprising hypertelorism, microcephaly, short palpebral fissures, inner epicanthal folds, and a short, turned-up nose. Often, the affected children have learning disorders and ADHD, and in some cases intellectual disability. Cardiac defects are also frequent. The entire syndrome occurs in up to 15 percent of babies born to women who regularly ingest large amounts of alcohol. Babies born to women who consume alcohol regularly during pregnancy have a high incidence of ADHD, learning disorders, and intellectual disability without the facial dysmorphism.

**Prenatal Drug Exposure.** Prenatal exposure to opioids, such as heroin, often results in infants who are small for their gestational age, with a head circumference below the tenth percentile and withdrawal symptoms that appear within the first 2 days of life. The withdrawal symptoms of infants include irritability, hypertonia, tremor, vomiting, a high-pitched cry, and an abnormal sleep pattern. Seizures are unusual, but the withdrawal syndrome can be life-threatening to infants if it is untreated. Diazepam (Valium), phenobarbital (Luminal), chlorpromazine (Thorazine), and paregoric have been used to treat neonatal opioid withdrawal. The long-term sequelae of prenatal opioid exposure are not fully known; the children’s developmental milestones and intellectual functions may be within the normal range, but they have an increased risk for impulsivity and behavioral problems. Infants prenatally exposed to cocaine are at high risk for low birth weight and premature delivery. In the early neonatal period, they may have transient neurological and behavioral abnormalities, including abnormal results on EEG studies, tachycardia, poor feeding patterns, irritability, and excessive drowsiness. Rather than a withdrawal reaction, the physiological and behavioral abnormalities are a response to the cocaine, which may be excreted for up to a week postnatally.

**Complications of Pregnancy.** Toxemia of pregnancy and uncontrolled maternal diabetes present hazards to the fetus and can potentially result in intellectual disability. Maternal malnutrition during pregnancy often results in prematurity and other obstetrical complications. Vaginal hemorrhage, placenta previa, premature separation of the placenta, and prolapse of the cord can damage the fetal brain by causing anoxia. The use of lithium during pregnancy was recently implicated in some congenital
malformations, especially of the cardiovascular system (e.g., Ebstein’s anomaly).

**Perinatal Period.** Some evidence indicates that premature infants and infants with low birth weight are at high risk for neurological and subtle intellectual impairments that may not be apparent until their school years. Infants who sustain intracranial hemorrhages or show evidence of cerebral ischemia are especially vulnerable to cognitive abnormalities. The degree of neurodevelopmental impairment generally correlates with the severity of the intracranial hemorrhage. Recent studies have documented that, among children with very low birth weight (less than 1,000 g), 20 percent had significant disabilities, including cerebral palsy, intellectual disability, autism, and low intelligence with severe learning problems. Very premature children and those who had intrauterine growth retardation were found to be at high risk for developing both social problems and academic difficulties. Socioeconomic deprivation can also affect the adaptive function of these vulnerable infants. Early intervention may improve their cognitive, language, and perceptual abilities.

**Acquired Childhood Disorders**

**Infection.** The most serious infections affecting cerebral integrity are encephalitis and meningitis. Measles encephalitis has been virtually eliminated by the universal use of measles vaccine, and the incidence of other bacterial infections of the CNS has been markedly reduced with antibacterial agents. Most episodes of encephalitis are caused by viruses. Sometimes a clinician must retrospectively consider a probable encephalitic component in a previous obscure illness with high fever. Meningitis that was diagnosed late, even when followed by antibiotic treatment, can seriously affect a child’s cognitive development. Thrombotic and purulent intracranial phenomena secondary to septicemia are rarely seen today except in small infants.

**Head Trauma.** The best-known causes of head injury in children that produces developmental handicaps, including seizures, are motor vehicle accidents, but more head injuries are caused by household accidents, such as falls from tables, open windows, and on stairways. Child maltreatment is not infrequently implicated in head traumas or intracranial trauma such as bleeding due “shaken baby” syndrome.

**Asphyxia.** Brain damage due to asphyxia associated with near drowning is not an uncommon cause of intellectual disability.

**Long-term Exposures.** Long-term exposure to lead is a well-established cause of compromised intelligence and learning skills. Intracranial tumors of various types and origins, surgery, and chemotherapy can also adversely affect brain function.

**Environmental and Sociocultural Factors**

Mild intellectual disability has been associated with significant deprivation of nutrition
and nurturance. Children who have endured these conditions are at risk for a host of psychiatric disorders including mood disorders, posttraumatic stress disorder, and attentional and anxiety disorders. Prenatal environment compromised by poor medical care and poor maternal nutrition may be contributing factors in the development of mild intellectual disability. Teenage pregnancies are at risk for mild intellectual disability in the baby due to the increased risk of obstetrical complications, prematurity, and low birth weight. Poor postnatal medical care, malnutrition, exposure to toxic substances such as lead, and potential physical trauma are additional risk factors for mild intellectual disabilities. Child neglect and inadequate caretaking may deprive an infant of both physical and emotional nurturances, leading to failure to thrive syndromes.

**DIAGNOSIS**

The diagnosis of intellectual disability can be made after the history is obtained, using information from a standardized intellectual assessment, and a standardized measure of adaptive function indicating that a child is significantly below the expected level in both areas. The severity of the intellectual disability will be determined on the basis of the level of adaptive function. A history and psychiatric interview are useful in obtaining a longitudinal picture of the child’s development and functioning. Examination of physical signs, neurological abnormalities, and in some cases, laboratory tests can be used to ascertain the cause and prognosis.

**History**

The clinician taking the history, which may elucidate pathways to intellectual disability, should pay particular attention to the mother’s pregnancy, labor, and delivery; the presence of a family history of intellectual disability; consanguinity of the parents; and known familial hereditary disorders.

**Psychiatric Interview**

A psychiatric interview of a child or adolescent with intellectual disability requires a high level of sensitivity in order to elicit information at the appropriate intellectual level while remaining respectful of the patient’s age and emotional development. The patient’s verbal abilities, including receptive and expressive language, can be initially screened by observing the communication between the caretakers and patient. If the patient communicates largely through gestures or sign language, the parents may serve as interpreters. Patients with milder forms of intellectual disability are often well aware of their differences from others and their failures, and may be anxious and ashamed during the interview. Approaching patients with a clear, supportive, concrete explanation of the diagnostic process, particularly patients with sufficiently receptive language ability, may allay anxiety and fears. Providing support and praise in language appropriate to the patient’s age and understanding is beneficial. Subtle direction,
structure, and reinforcement may be necessary to keep patients focused on the task or topic.

In general, the psychiatric examination of an intellectually disabled child or adolescent should reveal how the patient has coped with stages of development. Frustration tolerance, impulse control, and over-aggressive motor and sexual behavior are important areas of attention in the interview. It is equally important to elicit the patient’s self-image, areas of self-confidence, and an assessment of tenacity, persistence, curiosity, and willingness to explore the environment.

**Structured Instruments, Rating Scales and Psychological Assessment**

In children and adolescents who have acquired language, one of several standardized instruments that include numerous domains of cognitive function are used. For children ages 6 to 16 years, the Wechsler Intelligence Test for Children is typically administered, and for children ages 3 to 6 years, the Wechsler Preschool and Primary Scale of Intelligence-Revised is commonly used. The Stanford-Binet Intelligence Scale, Fourth Edition, has the advantage that it can be administered to children even younger, starting at age 2 years. The Kaufman Assessment Battery for Children can be used in children ages 2½ to 12½ years, whereas the Kaufman Adolescent and Adult Intelligence Test is applicable to a wide range of ages, from 11 to 85 years. All of the above standardized instruments evaluate cognitive abilities across multiple domains including verbal, performance, memory, and problem solving. Standardized instruments measuring adaptive function (functions of “everyday” life) are based on the construct that adaptive skills increase with age, and that adaptation may vary across different settings such as school, peer relationships, and family life. The Vineland Adaptive Behavior Scales can be used in infants through youth 18 years of age and includes four basic domains including *Communication* (Receptive, Expressive, and Written); *Daily Living Skills* (Personal, Domestic, and Community); *Socialization* (Interpersonal Relations, Play and Leisure, and Coping Skills); *Motor Skills* (Fine and Gross).

Several behavioral rating scales have been developed for the population with intellectual disability. General behavioral ratings scales include the Aberrant Behavior Checklist (ABC) and the Developmental Behavior Checklist (DBC). The Behavior Problem Inventory (BPI) is a good screening instrument for self-injurious, aggressive, and stereotyped behaviors. The Psychopathology Inventory for Mentally Retarded Adults (PIMRA) is utilized to identify the presence of comorbid psychiatric symptoms and disorders.

Examining clinicians can use several screening instruments for developmental and intellectual delay or disability in infants and toddlers. However, controversy over the predictive value of infant psychological tests is heated. Some report the correlation of abnormalities during infancy with later abnormal functioning as very low, and others report it to be very high. The correlation rises in direct proportion to the age of the child at the time of the developmental examination. Some exercises such as copying geometric figures, the *Goodenough Draw-a-Person Test*, the *Kohs Block Test*, and geometric puzzles
all may be used as quick screening tests of visual-motor coordination. The *Gesell* and *Bayley scales* and the *Cattell Infant Intelligence Scale* are most commonly used with infants.

The *Peabody Vocabulary Test* is the most widely used vocabulary test solely based on pictures. Other tests often found useful in detecting intellectual disability are the *Bender Gestalt Test* and the *Benton Visual Retention Test*. The psychological evaluation should assess perceptual, motor, linguistic, and cognitive abilities.

### Physical Examination

Various parts of the body may demonstrate identifying characteristics of specific perinatal and prenatal events or conditions associated with intellectual disabilities. For example, the configuration and the size of the head may offer clues to a variety of conditions, such as microcephaly, hydrocephalus, or Down syndrome. A patient’s facial characteristics, for example, hypertelorism, a flat nasal bridge, prominent eyebrows, epicanthal folds may provide clues to a recognizable syndrome such as FAS. Additional facial characteristics including corneal opacities, retinal changes, low-set and small or misshapen ears, a protruding tongue, and disturbance in dentition may be stigmata of a variety of known syndromes. Facial expression, color and texture of the skin and hair, a high-arched palate, the size of the thyroid gland, and the proportions of a child’s trunk and extremities may offer clues for particular syndromes. The circumference of the head should be measured as part of the clinical investigation. Dermatoglyphics may offer another diagnostic tool, because uncommon ridge patterns and flexion creases on the hand are often found in persons who are intellectually disabled. Abnormal dermatoglyphics occur in chromosomal disorders and in persons who were prenatally infected with rubella. *Table 31.3-4* lists syndromes with intellectual disability and their behavioral phenotypes.

<p>| Table 31.3-4 | Syndromes with Intellectual Disability and Behavioral Phenotypes |</p>
<table>
<thead>
<tr>
<th>Disorder</th>
<th>Pathophysiology</th>
<th>Clinical Features and Behavioral Phenotype</th>
</tr>
</thead>
<tbody>
<tr>
<td>Down syndrome</td>
<td>Trisomy 21, 95% nondisjunction, approx. 4% translocation; 1/1,000 live births; 1/2,500 in women less than 36 years old, 1.80 over 40 years old, 1.32 at 45 years old; possible overproduction of β-amyloid due to defect at 21q11.1</td>
<td>Hypotonia, upward-slanted palpebral fissures, midface depression, flat wide nasal bridge, simian crease, short stature, increased incidence of thyroid abnormalities and congenital heart disease. Passive, affable, hyperactivity in childhood, stubborn; verbal &gt; auditory processing, increased risk of depression, and dementia of the Alzheimer type in adulthood.</td>
</tr>
<tr>
<td>Fragile X syndrome</td>
<td>Inactivation of FMR-1 gene at Xq27.3 due to CGG base repeats, methylation; recessive; 1/1,000 male births, 1/3,000 female; accounts for 10–12% of intellectual disability in males.</td>
<td>Long face, large ears, midface hypoplasia, high arched palate, short stature, macroorchidism, mitral valve prolapse, joint laxity, strabismus. Hyperactivity, inattention, anxiety, stereotypies, speech and language delays, IQ decline, gaze aversion, social avoidance, shyness, irritability, learning disorder in some females; mild intellectual disability in affected females, moderate to severe in males; verbal IQ &gt; performance IQ.</td>
</tr>
<tr>
<td>Prader-Willi syndrome</td>
<td>Deletion in 15q12 (15q11–15q13) of paternal origin; some cases of maternal uniparental disomy; dominant in 1/10,000 live births; 90% sporadic; candidate gene: small nuclear ribonucleoprotein polypeptide (SNRPN)</td>
<td>Hypotonia, failure to thrive in infancy, obesity, small hands and feet, microcephalidism, cryptorchidism, short stature, almond-shaped eyes, fair hair and light skin, flat face, scoliosis, orthopedic problems, prominent forehead and bitemporal narrowing. Compulsive behavior, hyperphagia, hoarding, impulsivity, borderline to moderate intellectual disability, emotional lability, tantrums, excess daytime sleepiness, skin picking, anxiety, aggression.</td>
</tr>
<tr>
<td>Angelman syndrome</td>
<td>Deletion in 15q12 (15q11–15q13) of maternal origin; dominant; frequent deletion of γ-aminobutyric acid (GABA) B-3 receptor subunit, prevalence unknown but rare, estimated 1/20,000–1/30,000</td>
<td>Fair hair and blue eyes (66%); dysmorphic faces including wide smiling mouth, thin upper lip, and pointed chin; epilepsy (90%) with characteristic EEG; ataxia; small head circumference, 25% microcephalic. Happy disposition, paroxysmal laughter, hand flapping, clapping; profound intellectual disability; sleep disturbance with nighttime waking; possible increased incidence of autistic features; anecdotal love of water and music.</td>
</tr>
<tr>
<td>Cornelia de Lange syndrome</td>
<td>Lack of pregnancy associated plasma protein A (PAPPA) linked to chromosome 9q33; similar phenotype associated with trisomy 5p, ring chromosome 3; rare (1/40,000–1/100,000 live births); possible association with 3q26.3</td>
<td>Continuous eyebrows, thin downturned upper lip, microcephaly, short stature, small hands and feet, small upturned nose, arched nostrils, malformed upper lips, failure to thrive. Self-injury, limited speech in severe cases, language delays, avoidance of being held, stereotypic movements, twirling, severe to profound intellectual disability.</td>
</tr>
<tr>
<td>Williams syndrome</td>
<td>1/20,000 births; hemizygous deletion that includes elastin locus chromosome 7q11–23; autosomal dominant</td>
<td>Short stature, unusual facial features including broad forehead, depressed nasal bridge, stellate pattern of the iris, widely spaced teeth, and full lips; elfin-like faces; renal and cardiovascular abnormalities; thyroid abnormalities; hypercalcaemia. Anxiety, hyperactivity, fears, outgoing, sociable, verbal skills &gt; visual spatial skills.</td>
</tr>
<tr>
<td>Cri-du-chat syndrome</td>
<td>Partial deletion 5p; 1/50,000; region may be 5p15.2</td>
<td>Round face with hypertelorism, epicanthal folds, slanting palpebral fissures, broad flat nose, low-set ears, micrognathia; prenatal growth retardation; respiratory and ear infections; congenital heart disease; gastrointestinal abnormalities. Severe intellectual disability, infantile catlike cry, hyperactivity, stereotypies, self-injury. Broad face; flat midface; short, broad hands; small toes; hoarse, deep voice. Severe intellectual disability; hyperactivity; severe self-injury including hand biting, head banging, and pulling out finger- and toenails; stereotyped self-hugging; attention seeking; aggression; sleep disturbance (decreased REM).</td>
</tr>
<tr>
<td>Smith-Magenis syndrome</td>
<td>Incidence unknown, estimated 1/25,000 live births; complete or partial deletion of 17p11.2</td>
<td>Broad face; flat midface; short, broad hands; small toes; hoarse, deep voice. Severe intellectual disability; hyperactivity; severe self-injury including hand biting, head banging, and pulling out finger- and toenails; stereotyped self-hugging; attention seeking; aggression; sleep disturbance (decreased REM).</td>
</tr>
<tr>
<td>Rubinstein-Taybi syndrome</td>
<td>1/250,000, approx. male = female; sporadic; likely autosomal dominant; documented microdeletions in some cases at 16p13.3</td>
<td>Short stature and microcephaly, broad thumb and big toes, prominent nose, broad nasal bridge, hypertelorism, ptosis, frequent fractures, feeding difficulties in infancy, congenital heart disease, EEG abnormalities, seizures. Poor concentration, distractible, expressive language difficulties, performance IQ &gt; verbal IQ; anecdotally happy, loving, sociable, responsive to music, self-stimulating behavior; older patients have mood lability and temper tantrums.</td>
</tr>
</tbody>
</table>
Neurological Examination

Sensory impairments occur frequently among persons with intellectual disabilities. For example, hearing impairment occurs in 10 percent of persons with intellectual disability, a rate that is four times that of the general population. Visual disturbances can range from blindness to disturbances of spatial concepts, design recognition, and concepts of body image. Seizure disorders occur in about 10 percent of intellectually disabled populations and in one third of those with severe intellectual disability. Neurological abnormalities increase in incidence and severity in direct proportion to the degree of intellectual disability. Disturbances in motor areas are manifested in abnormalities of muscle tone (spasticity or hypotonia), reflexes (hyperreflexia), and involuntary movements (choreoathetosis). Less disability may also be associated with
Mild intellectual disability may not be recognized or diagnosed in a child until school challenges the child’s social and communication skills. Cognitive deficits include poor ability to abstract and egocentric thinking, both of which become more easily evident as a child reaches middle childhood. Children with milder intellectual disabilities may function academically at the high elementary level and may acquire vocational skills sufficient to support themselves in some cases; however, social assimilation may be problematic. Communication deficits, poor self-esteem, and dependence may further contribute to a relative lack of social spontaneity.

Moderate levels of intellectual disability are significantly more likely to be observed at a younger age, since communication skills develop more slowly and social isolation may ensue in the elementary school years. Academic achievement is usually limited to the middle-elementary level. Children with moderate intellectual deficits benefit from individual attention focused on the development of self-help skills. However, these children are aware of their deficits and often feel alienated from their peers and frustrated by their limitations. They continue to require a relatively high level of supervision but can become competent at occupational tasks in supportive settings.

Severe intellectual disability is typically obvious in the preschool years; affected children have minimal speech and impaired motor development. Some language development may occur in the school-age years. By adolescence, if language has not improved significantly, poor, nonverbal forms of communication may have evolved. Behavioral approaches are useful means to promote some self-care, although those with severe intellectual disability generally need extensive supervision.

Children with profound intellectual disability require constant supervision and are severely limited in both communication and motor skills. By adulthood, some speech development may be present, and simple self-help skills may be acquired. Clinical features frequently observed in populations with intellectual disability either in isolation or as part of a mental disorder, include hyperactivity, low frustration tolerance, aggression, affective instability, repetitive and stereotypic motor behaviors, and self-injurious behaviors. Self-injurious behaviors occur more frequently and with greater intensity in more severe intellectual disability.

Dylan was a full-term infant, the second child born to his 42-year-old mother, a medical technician, and 48-year-old father, a high school basketball coach. The pregnancy was unremarkable, and Dylan’s sister, who was two years older, was healthy and developing normally. The family lived in a rural town in the Midwest.

Dylan was an extremely fussy, active newborn with extended periods of crying that the pediatrician labeled classic colic. As a newborn, it was noticed that Dylan seemed to have large ears and strabismus, which the pediatrician said would probably resolve.
spontaneously. At 2 months of age, at a regular pediatric visit, a systolic heart murmur was heard and electrocardiography (ECG) revealed a mitral valve prolapse. Because Dylan was not cyanotic and had no other cardiac symptoms, no treatment was recommended except monitoring. Although Dylan became less fussy over time, he remained very active, did not sleep through the night, and was a picky eater, refusing solid foods.

Milestones were slightly delayed, with Dylan sitting unassisted at 10 months and walking at 18 months. Language was also delayed, and, although his first words appeared at 20 months, Dylan had always made his wants and needs known. Dylan’s parents were concerned about his activity level and his developmental delays compared with his sister; however, they were reassured by the pediatrician’s sense that boys often develop more slowly than girls in the first two years.

When Dylan was 3 years of age, his preschool teacher noted that he was unable to pay attention and he was hyperactive compared to his classmates, prompting his parents to obtain a developmental evaluation. Results showed modest delays in cognitive, linguistic, and motor functioning, with a developmental quotient (DQ) of 74. Dylan was described as inattentive, shy, and anxious, and he had poor eye contact. Enrolled in a special kindergarten, Dylan remained in a combination of special education and mainstreamed classes throughout his academic life.

At 7 years of age, the school psychologist evaluated Dylan and results indicated that he met criteria for a “learning disability” profile. Dylan had an overall IQ of 66, with close to average functioning in short-term memory and pronounced deficits in long-term memory, expressive language, and visual-spatial functioning. Dylan struggled with writing tasks and arithmetic, but loved science. Due to his significant problems with inattention and hyperactivity, Dylan was placed on Concerta, which was beneficial, and titrated up to 54 mg per day. He displayed transient, intense interests in unusual items, such as vacuum cleaners. When Dylan reached the older elementary grades, he began to have more difficulty socially, and he was bullied about being in special education, and teased for his long head and big ears.

As he entered adolescence, Dylan became increasingly anxious, so much so that he occasionally rubbed his hands or rocked, and he “fretted” about day-to-day issues and what would happen next. His long-term sensitivities to loud sounds seemed to wane slightly, but he developed fears of storm clouds and dogs and refused to ride on elevators. He became tearful and upset after his older sister left for a party, and worried that she might have a car accident. Dylan was very shy and would occasionally pace with worry and complain of stomachaches, but he attended school and had a small group of acquaintances in the Special Olympics bowling league. He enjoyed activities that did not involve much talking or sustained attention.

When Dylan was 17 years of age, his parents happened to watch a television documentary on genetic causes of intellectual disability. They were overwhelmed by the similarities between Dylan and some of the people described in the program. They later described the experience as a “jolt.” They had always accepted Dylan, quirks and all, and had stopped pushing their doctors for reasons “why” when Dylan was a
preschooler. Nevertheless, they immediately called the informational number offered in the show, and within 2 months, they had the genetic tests done that confirmed a diagnosis of fragile X syndrome.

Although Dylan’s day-to-day life did not change dramatically after the diagnosis, his parents reported a big difference in their approach to his shyness, restricted interests, and inattention. Dylan was later treated for anxiety with a selective serotonin reuptake inhibitor (SSRI) antidepressant, which decreased his social anxiety and facilitated activities with a few peers. Dylan’s parents reported a mixture of feelings at having such a late diagnosis—disappointment in their doctors, relief in finally knowing, and twinges of guilt. They were energized by Dylan’s positive responses to treatments for his attentional and anxiety symptoms and were pleased with Dylan’s recent increased interest in sharing activities with classmates and peers.

LABORATORY EXAMINATION

Laboratory tests that may elucidate the causes of intellectual disability include chromosomal analysis, urine and blood testing for metabolic disorders, and neuroimaging. Chromosomal abnormalities are the single most known common cause of intellectual disability.

Chromosome Studies

Chromosome analysis is commonly obtained when multiple physical anomalies, developmental delays, and intellectual disability present together. Current techniques are able to chromosomal regions with specific fluorescent in situ hybridization (FISH) markers, leading to microscopic deletions being identified in up to 7% of persons with moderate to severe intellectual disability. A history of growth retardation, the presence of microcephaly, a family history of intellectual disability, short stature, hypertelorism, and other facial abnormalities increase the risk for finding subtelomeric defects.

Amniocentesis, in which a small amount of amniotic fluid is removed from the amniotic cavity transabdominally at about the 15 weeks of gestation, has been useful in diagnosing prenatal chromosomal abnormalities. Its use is considered when an increased fetal risk exists, such as with increased maternal age. Amniotic fluid cells, mostly fetal in origin, are cultured for cytogenetic and biochemical studies.

Chronic villi sampling (CVS) is a screening technique to determine fetal chromosomal abnormalities. It is done at 8 to 10 weeks of gestation, 6 weeks earlier than amniocentesis is done. The results are available in a short time (hours or days) and, if the result is abnormal, the decision to terminate the pregnancy can be made within the first trimester. The procedure has a miscarriage risk between 2 and 5 percent; the risk in amniocentesis is lower (1 in 200). A non-invasive blood test called materniT21 is a proprietary prenatal test that detects abnormalities of chromosomes 21,18,13, X and Y. It is highly specific for Down syndrome (Figure 31.3-1). There is no risk of miscarriage.
Urine and Blood Analysis

Lesch-Nyhan syndrome, galactosemia, PKU, Hurler’s syndrome (Figure 31.3-2), and Hunter’s syndrome (Figure 31.3-3) are examples of disorders characterized by intellectual disability that can be identified through assays of the appropriate enzyme or organic or amino acids. Enzymatic abnormalities in chromosomal disorders, particularly Down syndrome, promise to become useful diagnostic tools.

FIGURE 31.3-3
Two brothers, age 6 and 8 years, with Hunter’s syndrome, shown with their normal older sister. They have had significant developmental delay, trouble with recurrent respiratory infection, and behavioral abnormalities. (Courtesy of L.S. Syzmanski, M.D., and A.C. Crocker, M.D.)
FIGURE 31.3-2
A 6-year-old girl with Hurler’s syndrome. Her care has involved a class for seriously multihandicapped children, attention to cardiac problems, and special counseling for patients. (Courtesy of L.S. Syzmanski, M.D., and A.C. Crocker, M.D.)

Electroencephalography
Electroencephalography is indicated whenever a seizure disorder is considered. “Nonspecific” EEG changes, characterized by slow frequencies with bursts of spikes and sharp or blunt wave complexes are found with greater frequency among populations with intellectual disability than in the general population; however, these findings do not elucidate specific diagnoses.

Neuroimaging
Neuroimaging studies with populations of intellectually disabled patients using either computerized tomography (CT) or magnetic resonance imaging (MRI) have found high rates of abnormalities in those patients with microcephaly, significant delay, cerebral palsy, and profound disability. Among patients with intellectual disability, neuroimaging is indicated, accompanying findings that suggest seizures, microcephaly or macrocephaly, loss of previously acquired skills, or neurologic signs such as dystonia, spasticity, or altered reflexes.

Although clinically not diagnostic, neuroimaging studies are currently also utilized to gather data that may eventually uncover biological mechanisms contributing to intellectual disability. Structural MRI, functional MRI (fMRI), and diffusion tensor imaging (DTI) are utilized in current research. For example, current data suggest that individuals with fragile X syndrome and concurrent attentional deficits are also more
likely to show aberrant frontal-striatal pathways on MRI than those patients without attentional problems. MRI is also useful to elucidate myelination patterns. MRI studies can also provide a baseline for comparison of a later, potentially degenerative process in the brain.

**Hearing and Speech Evaluations**

Hearing and speech should be evaluated routinely. Speech development may be the most reliable criterion in investigating intellectual disability. Various hearing impairments often occur in persons who are intellectually disabled, but in some instances hearing impairments can simulate intellectual disability. The commonly used methods of hearing and speech evaluation, however, require the patient’s cooperation and, thus, are often unreliable in severely disabled persons.

**COURSE AND PROGNOSIS**

Although the underlying intellectual impairment does not improve, in most cases of intellectual disability, level of adaptation increases with age and can be influenced positively by an enriched and supportive environment. In general, persons with mild and moderate mental intellectual disabilities have the most flexibility in adapting to various environmental conditions. Comorbid psychiatric disorders negatively impact overall prognosis. When psychiatric disorders are superimposed on intellectual disability, standard treatments for the comorbid mental disorders are often beneficial; however, less robust responses and increased vulnerability to side effects of psychopharmacologic agents are often the case.

**DIFFERENTIAL DIAGNOSIS**

By definition, intellectual disability must begin before the age of 18. In some cases, severe child maltreatment in the form of neglect or abuse may contribute to delays in development, which can appear to be intellectual disability. However these damages are partially reversible when a corrective, enriched, and stimulating environment is provided in early childhood. Sensory disabilities, especially deafness and blindness, can be mistaken for intellectual disability when a lack of awareness of the sensory deficit leads to inappropriate testing. Expressive and receptive speech disorders may give the impression of intellectual disability in a child of average intelligence, and cerebral palsy may be mistaken for intellectual disability. Chronic, debilitating medical diseases may depress and delay a child's functioning and achievement, despite normal intelligence. Seizure disorders, especially those that are poorly controlled, may contribute to persisting intellectual disability. Specific organic syndromes leading to isolated handicaps such as failure to read (alexia), failure to write (agraphia), or failure to communicate (aphasia), may occur in a child of normal and even superior intelligence. Children with learning disorders (which can coexist with intellectual disability) experience a delay or failure of development in a specific area, such as reading or
mathematics, but they develop normally in other areas. In contrast, children with intellectual disability show general delays in most areas of development.

Intellectual disability and autism spectrum disorder (ASD) often coexist; 70 to 75 percent of those with ASD have an IQ below 70. In addition, epidemiologic data indicate that ASD occurs in approximately 19.8% of persons with intellectual disability. Children with ASD have relatively more severe impairment in social relatedness and language than other children with the same level of intellectual disability.

A child younger than the age of 18 years with significant adaptive functional impairment, with an IQ less than 70, who also meets diagnostic criteria for dementia, will receive both a diagnosis of dementia and intellectual disability. However, a child whose IQ drops below 70 after the age of 18 years with newly acquired cognitive impairment will receive only the diagnosis of dementia.

TREATMENT

Interventions for children and adolescents with intellectual disability are based on an assessment of social, educational, psychiatric, and environmental needs. Intellectual disability is associated with a variety of comorbid psychiatric disorders that often require specific treatment, in addition to psychosocial support. Of course, when preventive measures are available, the optimal approach includes primary, secondary, and tertiary interventions.

Primary Prevention

Primary prevention comprises actions taken to eliminate or reduce the conditions that lead to development of intellectual disability, as well as associated disorders. For example, screening babies for PKU, and administrating a low phenylalanine diet when PKU is present, significantly alters the emergence of intellectual disability in those affected children. Additional primary prevention steps include education of the general public about strategies to prevent intellectual disability, such as abstinence from alcohol during pregnancy; continuing efforts of health professionals to ensure and upgrade public health policies; and legislation to provide optimal maternal and child health care. Family and genetic counseling helps reduce the incidence of intellectual disability in a family with a history of a genetic disorder.

Secondary and Tertiary Prevention

Prompt attention to medical and psychiatric complications of intellectual disability can diminish their course (secondary prevention) and minimize the sequelae or consequent disabilities (tertiary prevention). Hereditary metabolic and endocrine disorders, such as PKU and hypothyroidism, can be treated effectively in an early stage by dietary control or hormone replacement therapy.

Educational Interventions. Educational settings for children with intellectual
disability should include a comprehensive program that addresses academics and training in adaptive skills, social skills, and vocational skills. Particular attention should focus on communication and efforts to improve the quality of life.

**Behavioral and Cognitive-Behavioral Interventions.** The difficulties in adaptation among the intellectual disability populations are widespread and so varied that several interventions alone or in combination may be beneficial. Behavior therapy has been used for many years to shape and enhance social behaviors and to control and minimize aggressive and destructive behaviors. Positive reinforcement for desired behaviors and benign punishment (e.g., loss of privileges) for objectionable behaviors has been helpful. Cognitive therapy, such as dispelling false beliefs and relaxation exercises with self-instruction, has also been recommended for intellectually disabled persons who can follow the instructions. Psychodynamic therapy has been used with patients and their families to decrease conflicts about expectations that result in persistent anxiety, rage, and depression. Psychiatric treatment modalities require modifications that take into consideration the patient’s level of intelligence.

**Family Education.** One of the most important areas that a clinician can address is educating the family of a child or adolescent with intellectual disability about ways to enhance competence and self-esteem while maintaining realistic expectations for the patient. The family often finds it difficult to balance the fostering of independence and the providing of a nurturing and supportive environment for an intellectually disabled child, who is likely to experience some rejection and failure outside the family context. The parents may benefit from continuous counseling or family therapy and should be allowed opportunities to express their feelings of guilt, despair, anguish, recurring denial, and anger about their child’s disorder and future. The psychiatrist should be prepared to give the parents all the basic and current medical information regarding causes, treatment, and other pertinent areas (e.g., special training and the correction of sensory defects).

**Social Intervention.** One of the most prevalent problems among persons with intellectual disability is a sense of social isolation and social skills deficits. Thus, improving the quantity and quality of social competence is a critical part of their care. Special Olympics International is the largest recreational sports program geared for this population. In addition to providing a forum to develop physical fitness, Special Olympics also enhances social interactions, friendships, and (it is hoped) general self-esteem. A recent study confirmed positive effects of the Special Olympics on the social competence of the intellectually disabled adults who participated.

**Psychopharmacologic Interventions.** Pharmacological approaches to the treatment of behavioral and psychological symptoms in children with intellectual disability follow the paradigms of the evidence-based literature on treatment for all children with psychiatric disorders. However, given the paucity of randomized trials in
the childhood intellectual disability population, an empirical approach must also be taken.

COMMON COMORBID PSYCHIATRIC SYMPTOMS AND DISORDERS

Aggression, Irritability, and Self-injurious Behavior. Risperidone has been well documented as an efficacious treatment for irritability (aggression, self-injury, and severe tantrums) in children with ASD by the Research Units on Pediatric Psychopharmacology (RUPP, Autism Network 2002). Risperidone is helpful in treating disruptive behaviors in children with below-average intelligence, and has a good overall safety and tolerability profile. Cognitive testing has demonstrated small but significant improvement in cognitive ability with risperidone use. Children and adolescents with intellectual disability appear to be at higher risk for the development of tardive dyskinesia after use of antipsychotic medications; however, the atypical antipsychotics, including risperidone and clozapine (Clozaril), may provide some relief with a decreased risk of tardive dyskinesia.

There is evidence to support the use of antipsychotic agents in the management of self-injurious behavior (SIB). Although data exist on the efficacy of thioridazine in improving SIB, a “black box” warning regarding QT prolongation with thioridazine has drastically diminished use of this drug, and atypical antipsychotic agents are currently preferred.

Attention-Deficit/Hyperactivity Disorder. Estimates of attention deficit/hyperactivity (ADHD) and ADHD-like symptoms among children with sub average intelligence, genetic disorders, and developmental delay is estimated to be significantly higher than rates in the community. Randomized clinical trials of several psychopharmacologic agents have been done in children with sub-average intelligence. These include trials with methylphenidate, clonidine, and risperidone. The existing data for the treatment of ADHD and ADHD-like symptoms in youth with sub-average intelligence and developmental disorders suggest that agents, particularly stimulants used to treat ADHD in typically developing children, provide some degree of benefit to children with intellectual disability and ADHD. However, the occurrence of side effects within this population appears to be greater than in children with ADHD in the community. Thus, recommendations regarding treatment of ADHD in children and adolescents with comorbid ADHD include close monitoring for side effects. Studies of methylphenidate (Ritalin) treatment in those mildly intellectually disabled with ADHD have shown significant improvement in the ability to maintain attention and to stay focused on tasks. Methylphenidate treatment studies have not shown evidence of long-term improvement in social skills or learning. Risperidone also has been found to be beneficial in reducing symptoms of ADHD in this population; however, it may produce an increase in serum prolactin level. It is prudent to begin with a trial of a stimulant medication before the use of antipsychotic agents for the treatment of ADHD symptoms in intellectual disorder. A new extended release methylphenidate oral suspension (Quillivant XR, 2013) is currently available in 25 mg/5 ml preparation, and is taken
once daily for the treatment of ADHD in children 6 to 12 years of age.

Amphetamine-based preparations have been shown to be efficacious in treating ADHD in typically developing children; however, it does not appear that these stimulant preparations have been specifically studied in children with intellectual disability. Clonidine has been used clinically in this population, especially to ameliorate hyperactivity and impulsivity. Although there are scant data, clinical ratings by parents and clinicians suggest its efficacy.

Atomoxetine has been shown to be efficacious in children diagnosed with ASD and prominent ADHD features, and it is used clinically in the intellectually disabled population.

**Depressive Disorders.** The identification of depressive disorders among individuals with intellectual disability requires careful evaluation, since it may be inadvertently overlooked when behavioral problems are prominent. There have been anecdotal reports of disinhibition in response to SSRIs (e.g., fluoxetine [Prozac], paroxetine [Paxil], and sertraline [Zoloft]) in intellectually disabled individuals with ASD. Given the relative safety of SSRI antidepressants, a trial is indicated when a depressive disorder is diagnosed in a child or adolescent with intellectual disability.

**Stereotypical Motor Movements.** Antipsychotic medications—historically, haloperidol (Haldol) and chlorpromazine, and currently, the atypical antipsychotics—are used in the treatment of repetitive self-stimulatory behaviors in children with intellectual disability when these behaviors are either harmful to the child or disruptive. Anecdotal reports indicate that these agents may diminish self-stimulatory behaviors; however, there is no improvement seen in adaptive behavior. Obsessive-compulsive symptoms often overlap with the repetitive stereotypical behaviors seen in children and adolescents with intellectual disability, particularly in those with comorbid ASD. SSRIs such as fluoxetine, fluvoxamine (Luvox), paroxetine, and sertraline have been shown to have efficacy in treating obsessive-compulsive symptoms in children and adolescents and may have some efficacy for stereotyped motor movements.

**Explosive Rage Behavior.** Antipsychotic medications, particularly risperidone, have been shown to be efficacious for the treatment of explosive rage. Systematic controlled studies are indicated to confirm the efficacy of these drugs in the treatment of rage outbursts. β-Adrenergic receptor antagonists (beta-blockers), such as propranolol (Inderal), have been reportedly anecdotally to result in fewer explosive rages in some children with intellectual disability and ASD.

**SERVICES AND SUPPORT FOR CHILDREN WITH INTELLECTUAL DISABILITY**

**Early Intervention**

Early intervention programs serve individuals for the first 3 years of life. Such services are generally provided by the state and begin with a specialist visiting the home for
several hours per week. Since the passage of Public Law 99–447, the Education of the Handicapped Amendments of 1986, early intervention services for the entire family are emphasized. Agencies are required to develop an Individualized Family Service Plan (IFSP) for each family, which identifies specific interventions to best help the family and child.

School

From ages 3 to 21 years, school is responsible by law to provide appropriate educational services to children and adolescents with intellectual disability in the United States. These mandates were created by the passage of Public Law 94–142, the Education for All Handicapped Children Act of 1975, and expanded with the addition of the Individuals with Disabilities Act (IDEA) of 1990. Through these laws, public schools must develop and provide an individualized educational program for each student with intellectual disability, determined at a meeting designated as the Individualized Education Plan (IEP) with school personnel and the family. The education must be provided for the child in the “least restrictive environment” that will allow the child to learn.

Supports

A wide variety of organized groups and services are available for children with intellectual disability and their families. These include short-term respite care, which allow families a break and is generally set up by state agencies. Other programs include the Special Olympics, which allows children with intellectual disability to participate in team sports and in sports competitions. Many organizations also exist for families who wish to connect with others who have children with intellectual disability.

REFERENCES

Communication disorders range from mild delays in acquiring language to expressive or mixed receptive–expressive disorders, phonological disorders, and stuttering, which may remit spontaneously or persist into adolescence or even adulthood. Language delay is one of the most common very early childhood developmental delays, affecting up to approximately 7 percent of 5-year-olds. The rates of language disorders are understandably higher in preschoolers than in school-age children; rates were reported to be close to 20 percent of 4-year-olds in the Early Language in Victoria Study (ELVS). To communicate effectively, children must have a mastery of multiple aspects of language—that is, the ability to understand and express ideas—using words and speech, and express themselves in vernacular language. In the Fifth Edition of the *American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), Language Disorder includes both expressive and mixed receptive–expressive problems. DSM-5 speech disorders include Speech Sound Disorder (formerly known as Phonological Disorder) and Childhood-Onset Fluency Disorder (Stuttering). Children with expressive language deficits have difficulties expressing their thoughts with words and sentences at a level of sophistication expected for their age and developmental level in other areas. These children may struggle with limited vocabularies, speak in sentences that are short or ungrammatical, and often present descriptions of situations that are disorganized, confusing, and infantile. They may be delayed in developing an understanding and a
memory of words compared with others their age. Children with language disorder are at higher risk for developing reading difficulties. Current expert consensus considers reading comprehension impairment a form of language impairment, distinct from other reading deficits such as dyslexia.

Language and speech are pragmatically intertwined, despite the distinct categories of language disorders and speech disorders in DSM-5. Language competence spans four domains: phonology, grammar, semantics, and pragmatics. **Phonology** refers to the ability to produce sounds that constitute words in a given language and the skills to discriminate the various phonemes (sounds that are made by a letter or group of letters in a language). To imitate words, a child must be able to produce the sounds of a word. **Grammar** designates the organization of words and the rules for placing words in an order that makes sense in that language. **Semantics** refers to the organization of concepts and the acquisition of words themselves. A child draws from a mental list of words to produce sentences. Children with language impairments exhibit a wide range of difficulties with semantics that include acquiring new words, storage and organization of known words, and word retrieval. Speech and language evaluations that are sufficiently broad to test all of the preceding skill levels will be more accurate in evaluating a child’s remedial needs. **Pragmatics** has to do with skill in the actual use of language and the “rules” of conversation, such as pausing so that a listener can answer a question and knowing when to change the topic when a break occurs in a conversation. By age 2 years, toddlers without speech or language delay may know a few words or up to 200 words, and by age 3 years, most children understand the basic rules of language and can converse effectively. Table 31.4a-1 provides an overview of typical milestones in language and nonverbal development.

---

### Table 31.4a-1

**Normal Development of Speech, Language, and Nonverbal Skills in Children**

---
Over the last decade there have been an increasing number of investigative studies of speech and language interventions with positive outcomes identified in numerous areas of language. These include improvements in expressive vocabulary, syntax usage, and overall phonologic development. Most interventions are targeted strategies for the child’s particular deficit, and delivered by speech and language therapists.

</table>

Language disorder consists of difficulties in the acquisition and use of language across many modalities, including spoken and written, due to deficits in comprehension or production based on both expressive and receptive skills. These deficits include reduced vocabulary, limited abilities in forming sentences using the rules of grammar, and impairments in conversing based on difficulties using vocabulary to connect sentences in descriptive ways.

**EXPRESSION LANGUAGE DEFICITS**
